PRELIMINARY RESULTS REGARDING VASCULAR ENDOTHELIAL GROWTH FACTOR (VEGF-A) LEVELS IN THE SERUM OF GASTRIC CANCER PATIENTS (Abstract): The most studied VEGF molecule is VEGF-A (Vascular Endothelial Growth Factor). Its involvement in various neoplastic processes represents an intensely controversial hypothesis. **Material and methods:** This is a prospective study extending over a period of 7 months, and including 38 hospitalized patients who underwent surgery for gastric cancer between 01/01/2011 – 07/01/2011, at the Surgery Departments of the Emergency Clinical County Hospital Mureş. Survival rate was determined based on age and gender of the patients, the macroscopic and microscopic appearance of the tumor, and pT, N, M parameters of the resected specimens. All these tumor parameters were correlated with preoperative VEGF-A levels, measured at the Central Laboratory of the Emergency Clinical County Hospital Mureş, using plasma samples and a human VEGF ELISA kit with cross-reactivity with VEGF 165 (*BioLife Group*), according to the instructions provided by the manufacturer. No enrolled patient had any preoperative treatment. In order to establish the reference value for VEGF-A in serum, we tested a group of 14 apparently healthy persons, and we calculated a mean value. **Results:** The reference value for VEGF-A in serum was 157.3 pg/ml. In gastric cancer patients the preoperative VEGF-A levels were 376, 188±247.11, showing significant elevation vs. the control group ($p<0.001$), but it did not correlate with any of the tested tumor parameters. Survival rate displayed statistical correlation with histological type of the tumor, and VEGF-A serum levels, so that patients with intestinal type gastric cancer showed a superior survival vs. those with diffuse type ($p=0.0043$). A better survival was noted in patients with VEGF-A serum levels over the threshold value of 173 pg/ml. **Discussion and conclusions:** The VEGF-A levels in serum are significantly increased preoperatively in gastric cancer patients, compared to apparently healthy persons, but they dot show correlation with tumor parameters. As a result it cannot be used as prognostic factor, but it may be an evolution marker. Survival rate is significantly higher in intestinal type gastric cancers, ads compared to the diffuse type, as well as in patients with serum VEGF-A values over the threshold value. **Key words:** GASTRIC CANCER, VASCULAR ENDOTHELIAL GROWTH FACTOR, SERUM LEVELS, SURVIVAL, TUMOR PARAMETERS, CORRELATION

Semnificația prognostică a nivelului seric a factorului de creştere a endoteliului vascular (VEGF-A), este în atenția numeroaselor

cercetări recente dar rezultatele sunt controversate (1,2,3,4) şi asocierea numeroaselor efecte secundare terapiei antiangiogenice fac din angiogeneza tumorală un subiect de mare actualitate în literatură.

În ceea ce priveşte cancerul gastric, sunt autori care susţin că nivelul seric crescut a VEGF-A se corelează cu, profunzimea invaziei tumorale şi stadiul tumorii, prezenţa metastazelor la distanţă constituind un factor prognostic independent (5, 6, 7).

MATERIAL ŞI METODĂ

În studiul de faţă am analizat nivelul seric a VEGF la pacienţii cu cancer gastric, în raport cu factorii clinico-patologici.

Studiul prospectiv a fost efectuat pe o durată de 7 luni, şi a inclus 38 de pacienţi internaţi şi operaţi cu cancer gastric în perioada 01.01.2011-01.07. 2011, în cadrul secţiilor de chirurgie ale Spitalului Clinic Judeţean de Urgenţă Mureş. Nici un pacient inclus în studiu nu a beneficiat de tratament preoperator, iar pentru determinarea nivelului seric a VEGF-A, la toţi pacienţii incluşi li s-a prelevat sânge preoperator. În vederea determinării valorii serice de referinţă pentru VEGF-A, s-a recoltat sânge şi de la un lot de 14 persoane aparent sănătoase.

Pentru recoltarea probelor s-a obţinut consimţământul pacienţilor şi menţionez că studiul a primit aprobarea Comitetului de Etică al Universităţii de Medicină şi Farmacie Tg. Mureş.

Determinarea serică a nivelului VEGF-A s-a realizat în cadrul Laboratorului Central al Spitalului Clinic Judeţean de Urgenţă Mureş, şi s-au utilizat probele de plasmă şi kitul ELISA VEGF human cu reactivitate încrucişată pentru VEGF 165 (*BioLife Group*) conform instrucţiunilor date de producător.

Datele au fost obţinute din foile de observaţii, buletinele histopatologice, şi în urma anamnezei pacienţilor, iar parametrii analizaţi au fost: vârsta, sexul pacienţilor, aspectul macroscopic şi microscopic al tumorii, stadializarea conform sistemului pTNM, nivelul seric al VEGF, supravieţuirea pe termen scurt a pacienţilor cu cancer gastric.

Pentru clasificarea pTNM s-a utilizat cea de a 7-a stadializare AJCC intrată în uz în 2010. Pentru studiul statistic am utilizat programele *GraphPad* şi *Microsoft Excel*.

REZULTATE

1. Determinarea valorii serice de referinţă a VEGF-A

Valoarea medie de referinţă la persoanele aparent sănătoase a fost de 157,3 pg/ml.

2. Parametrii clinico-patologici ai pacienţilor cu cancer gastric

Din cei 38 de pacienţi incluşi în studiu, 7 cazuri au fost limfoame gastrice (18,43 %), şi 31 de pacienţi au prezentat carcinoame gastrice (81,57%). În studiul de faţă am analizat doar cazurile de carcinoame gastrice, limfoamele fiind excluse.

S-a observat predominanţa tipului masculin totalizând 20 de cazuri (64,52%), în defavoarea celui feminin reprezentat de 11 cazuri (35,48%) şi un raport bărbaţi/femei de 1,8:1.

În ceea ce priveşte vârsta 18 pacienţi aveau peste 65 de ani (58,06%) şi 13 sub 65 de ani (41,94%). Din cele 31 de carcinoame, 16 (51,62%) au fost localizate antral şi 15 (48,38%) la nivelul corpului gastric. Conform clasificării Lauren, 25 de cazuri au fost carcinoame de tip intestinal (80,65%) şi 6 carcinoame difuze (19,35%).

Majoritatea cazurilor au fost diagnosticate în stadiul pN3, respectiv 18 cazuri (58,06%), şi doar 5 cazuri (16,14%) au fost în stadiul pN2, respectiv 8 cazuri (25,80%)

în pN-1.

64,52% din cazuri au fost încadrate în stadiul pT4. Nu s-a înregistrat nici un caz în pT1.

3. Determinarea valorii serice a VEGF la pacienții cu cancer gastric

Media valorilor serice a VEGF-A înregistrată în rândul pacienților cu cancer gastric este semnificativ mai mare față de media obținută la lotul control, ($p<0,001$) după cum se poate observa în tabelul I.

Nu s-a înregistrat o diferență semnificativă între valorile serice ale VEGF în raport cu vârsta şi sexul pacienților, localizarea tumorii, tipul histologic, gradul invaziei tumorale, numărul de grupuri limfatice invadate. Datele obținute sunt prezentate în tabelul II.

TABELUL I

Valorice serice pentru VEGF

Media valorilor VEGF pentru lotul control	Media valorilor VEGF preoperator, pentru lotul de studiu	Valoarea lui p
157,39±68.5,	376, 188±247,11	p<0,001

TABELUL II

Analiza nivelului seric de VEGF în raport cu factorii clinico-patologici studiați

Factori clinico-patologici		Media valorilor VEGF	Valoarea lui p
Sex	Masculin	393,41±235,91,	Testul t student p=0,6091
	Feminin	344,86±275,27	
Vârstă	>65 ani	370,83±266,38	Test Mann Whitney p=0,7793
	<65 ani	383,59±228,11	
Localizarea tumorii	Antru	379,14±264,94	p=0,9466
	Corp	373,03±255,91	
Tipul histologic	Intestinal	365,12±208,75	Test Mann Whitney p=0,8265
	Difuz	421,770±392,58

	T3-T4	411,68±269,77	

Rata supraviețuirii

În lotul studiat am înregistrat 7decese (22,58%). Am considerat mortalitatea intraspitalicească, în primele 30 de zile postoperator. La 1,5 luni de la operație s-au înregistrat 2 decese, la 2 luni tot 3 decese, iar la 3 şi respectiv 4 luni câte un deces.

Pentru a studia supraviețuirea pe termen

scurt a pacienților în funcție de vârstă am împărțit lotul studiat în 2 subloturi: 13 pacienți cu vârste sub 65 de ani (41,94%) şi 18 de pacienți cu vârsta peste 65 de ani (58,06%). Rata supraviețuirii nu diferă semnificativ în raport cu vârsta (p=0,3942).

Nu am obținut o diferență semnificativă privind rata de supraviețuire în funcție de sex. (p=0,7046), şi nici în ceea ce priveşte localizarea tumorii primare (p=0,6648).

Am înregistrat o diferență semnificativă statistic privind tipul histopatologic al tumorii, astfel rata de supraviețuire în rândul pacienților cu cancer gastric de tip intestinal a fost mai mare comparativ cu rata de supraviețuire pentru tipul difuz (p=0,0043)

Am considerat nivelul prag VEGF(cut-off), ca fiind valoarea ce depăşeşte 95% din valorile înregistrate pentru lotul martor. Pentru studiul nostru această valoare a fost de 173pg/ml. Pacienții la care s-au înregistrat valori serice de VEGF-A peste valoarea prag de 173 pg/ml au fost considerați VEGF-A pozitivi (+), iar cei cu valori sub 173 pg/ml, VEGF-A negativi (-). Astfel din 31 de cazuri incluse în studiu, în 24 de cazuri (77,42%) valoarea serică VEGF-A a fost peste valoarea prag şi în 7 cazuri (22,58%) sub această valoare.

Rata de supraviețuire pentru pacienții VEGF + a fost mai mare (75%), comparativ cu rata de supraviețuire înregistrată la pacienții cu VEGF - (85,71%) În urma analizei seriei de factori clinico-patologici clasici, s-a observat predominanța carcinoamelor de tip intestinal, şi a cazurilor încadrate ca pT4 şi pN3, acest aspect constituind un semnal de alarmă în ceea ce priveşte capacitatea de diagnosticare precoce a cancerului gastric.

În privința aspectelor referitoare la nivelul seric a VEGF-A, o serie de autori au evaluat nivelul seric a VEGF-A, ca factor prognostic în diferite procese neoplazice, iar o parte din valorile serice de referință obținute de aceştia pentru lotul control sunt redate în tabelul III.

TABELUL III

Valoarea serică a VEGF la lotul control

Valoare de referință lot control VEGF seric		**Autor**
178,4 pg/ml (110,3-159,5 pg/ml)	Circulating levels of VEGF family and their receptors in hepatocelullar carcinoma (9)	Kemic O ş i colab, 2010
141 pg/ml (76-209 pg/ml).	Factori predictive în evoluția sindromului de detresă respiratorie (10)	Solomon SR, 2011
346.9 pg/ml (31.1-630.6 pg/ml)	Measurement of circulating levels of VEGF-A, -C, and –D and their receptors, VEGF-1 and -2 in gastric adenocarcinoma (11)	Mansour S Al-Moundhri şi colab, 2008
186 (101–266) pg/ml	Circulating VEGF levels in the serum of gastric cancer patients (6)	Karayiannakis AJ., 2002
167.5 pg/ml (101.5–245.3) pg/ml	Serum Vascular Endothelial Growth Factor in Breast Cancer. Its Relation with Cancer Type and Estrogen Receptor Status (12)	Heer K. şi colab, 2001
157.3 pg/ml (75-274) pg/ml		

Valoarea serică de referinţa pentru VEGF-A înregistrată în studiul nostru a fost raportată la literatura de specialitate, însă în vederea unei interpretării obiective am utilizat în analiza statistică valorile proprii.

Menţionez că s-a evidenţiat o diferenţă semnificativă între nivelul seric a VEGF înregistrat la pacienţii cu cancer gastric, care este mult crescut, comparativ cu valoarea de referinţă a lotului control, aspect confirmat de mai mulţi autori (7,13,14).

Datele din literatură demonstrează un prognostic favorabil pentru tumorile bine diferenţiate, care înregistrează o rată de supravieţuire semnificativ mai bună comparativ cu cele slab diferenţiate (15,16).

Sung Y Oh şi colaboratorii într-un studiu în 2008 au arătat că nivelul seric preoperator a VEGF se corelează cu mărimea tumorii, şi prezenţa invaziei limfatice (17).

Karayiannakis AJ şi colaboratorii într-un studiu realizat în anul 2002 au raportat că nivelul seric pentru VEGF se corelează direct cu gradul infiltrării tumorale, stadiul TNM şi prezenţa metastazelor la distanţă (6).

Printr-o analiză multivariată au demonstrat ca nivelul seric VEGF reprezintă un factor prognostic nefavorabil alături de factorii clinico-patologici clasici (localizarea tumorii, gradul tumoral de infiltrate, stadiul TNM, prezenţa invaziei limfatice, prezenţa metastazelor la distanţă).

FDA (*US Food and Drug Administration*) a stopat tratamentul cu Avastin (Bevacizubam) în cancerul mamar, având în vedere faptul că nu s-au înregistrat îmbunătăţiri privind rata de supravieţuire mai mult decât atât s-au înregistrat şi o serie de efecte adverse

În ceea ce priveşte cancerul gastric Atsushi Ohtsu şi colaboratorii într-un studiu realizat în anul 2011, au arătat că rata supravieţuirii pentru pacienţii cărora li s-a administrat tratament chimioterapic asociat cu Avastin este semnificativ mai mare comparativ cu pacienţii la care s-a administrat doar tratament chimioterapic (18).

CONCLUZII

Nivelul seric de VEGF-A este semnificativ crescut în rândul pacienţilor cu cancer gastric comparativ cu lotul control, însă acesta nu se corelează cu nici unul dintre parametrii clinico-patologici clasici analizaţi.

Pacienţii cu carcinoame de tip intestinal şi niveluri serice crescute ale VEGF-A prezintă supravieţuire mai bună.

Nivelul seric de VEGF nu poate fi utilizat ca factor prognostic în cancerul gastric, însă poate fi utilizat ca factor evolutiv.

EVOLUTION OF NUTRITIONAL STATUS AND LIPID METABOLISM PARAMETERS IN GLUTEN FREE DIET (Abstract): Celiac disease is one of the most common forms of food intolerance in children, being an autoimmune enteropathy occurring in genetically susceptible individuals. The only treatment of celiac disease consists in a lifelong strict gluten-free diet. After gluten free diet patients with normal weight or growth failure risk become obese on the one hand because of recovery intestinal absorption and, on the other hand, nutritionally unbalanced diet, high in fat and protein. **Aim**: the aim of this study was to assess the nutritional status and the presence and prevalence of various changes dyslipidemia in gluten free diet. **Material and methods:** the trial was formed by 92 patients (mean age at diagnosis 88,5 months) diagnosed with CD between January 2008 – December 2010 in 2nd and 3rd Pediatric Clinics of "Sf. Maria" Hospital Iaşi. Patients were divided into two groups: group I included 36 patients younger than 2 years and group II included 52 patients aged over 2 years at time of diagnosis of celiac disease. All patients received gluten free diet. Were evaluated periodically anthropometric indices (weight, height, body mass index and Z scores in children over 2 years and weight and nutritional index in children under 2 years) and lipid profile (total lipids, total cholesterol, HDL cholesterol, triglycerides). Assessing food intake was achieved by interviewing parents and children on dietary habits and daily food ration. **Results:** Assessment of nutritional status: group I: - after 24 months of gluten free diet 5 cases presented overweight; group II: after 24 months of gluten free diet obesity (BMI> 30) was found in 16.07% of cases (9 patients) and overweight (BMI> 25) was found in 28.57% of cases (16 patients). Food intake: in all cases was observed increased calorie intake by an excess of lipids and carbohydrates in the diet. Investigation of lipid metabolism: in group II high values of cholesterol were found in 12 cases (21,42 of cases). In conclusions, in celiac disease gluten free diet should be balanced caloric, fat and protein to ensure an optimal nutritional status and prevent long-term complications. **Key words**: CELIAC DISEASE, GLUTEN FREE DIET, OBESITY, DYSLIPIDEMIA, CHILDREN.

Boala celiacă (BC) reprezintă una din cele mai frecvente forme de intoleranță alimentară la copil, fiind definită ca o enteropatie permanentă, imunomediată, declanşată la indivizii susceptibili genetic de prezența glutenului în alimentație. Singurul tratament al BC este reprezentat de excluderea glutenului pe toată durata vieții din

alimentație (1).

După inițierea regimului fără gluten (RFG) pacienții cu greutate normală sau cu falimentul creşterii în momentul diagnosticării riscă să devină obezi pe de o parte datorită refacerii absorbției intestinale şi, pe de lată parte, datorită dietei necorespunzătoare, bogată în lipide şi proteine (2).

Scopul studiului a fost de a evalua statusul nutrițional precum şi prezența şi prevalența diferitelor modificări dislipidemice la copiii diagnosticați cu BC în timpul RFG.

MATERIAL ŞI METODE

Am realizat un studiu prospectiv în care au fost incluşi 92 de pacienți diagnosticați cu boală celiacă în Clinicile a II-a şi a III-a Pediatrie a Spitalului de Copii „Sfânta Maria" din Iaşi în perioada 2005-2010. Vârsta pacienților a fost cuprinsă între 19 luni şi 127 luni (vârsta medie 88,5 luni). Diagnosticul de BC s-a stabilit pe baza criteriilor revizuite ale *Societății Europene de Gastroenterologie, Hepatologie şi Nutriție Pediatrică*. Pacienții au fost împărțiți în două loturi: lotul I a cuprins 36 de pacienți cu vârsta sub 2 ani şi lotul II în care au fost incluşi 56 de pacienți cu vârsta peste 2 ani în momentul stabilirii diagnosticului de BC. Toți pacienții au primit RFG şi tratamentul carențelor nutriționale secundare malabsorbției intestinale. S-au evaluat periodic (la intervale de 6 luni) indicii antropometrici (greutatea, talia, indicele de masă corporală şi scorul Z la copiii peste 2 ani şi indicele ponderal şi nutrițional la copiii cu vârsta sub 2 ani), precum şi profilul lipidic (lipide totale, colesterol total, HDL colesterol, trigliceride). Interpretarea rezultatelor s-a efectuat prin raportarea la valorile normale pentru vârstă şi sex. Aprecierea aportului alimentar s-a realizat prin chestionarea părinților şi a copiilor privind obiceiurile alimentare şi rația alimentară zinică în care s-a urmărit aportul de calorii, lipide, proteine, vitamine.

Lotul martor a cuprins un număr egal de subiecți cu vârstă şi sex corespunzătoare lotului studiat, IMC calculat fiind între percentila 25-75 pentru vârstă şi sex.

REZULTATE

1. Evaluarea statusului nutrițional Lotul I: la pacienții cu vârsta sub 2 ani în momentul stabilirii diagnosticului de BC a predominat malnutriția protein-calorică (MPC) de gradul II în 58,33% din cazuri (fig. 1).

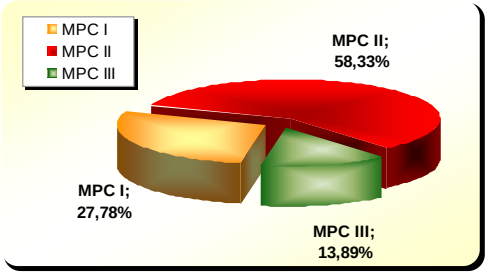

Fig. 1. Deficitul ponderal la pacienții cu vârsta sub 2 ani

În timpul RFG curba ponderală a fost ascendentă: după 1 lună de RFG pacienții cu MPC gradul I şi-au reluat creşterea în greutate, curba ponderală devenind ascendentă după 2-6 săptămâni, pentru ca după 6-12 luni greutatea corpului să ajungă la valori corespunzătoare vârstei în 55.83% din cazuri (fig.2).

În 5 cazuri cu MPC gradul III deficitul ponderal s-a menținut după 6 luni, la aceştia pe lângă deficitul proteic asociindu-se şi carențele vitaminice, minerale, hormonale, recuperarea nutrițională necesitând o perioadă mai lungă de timp.

După 24 de luni de RFG excesul ponderal (IP>1) a fost întâlnit în 5 cazuri.

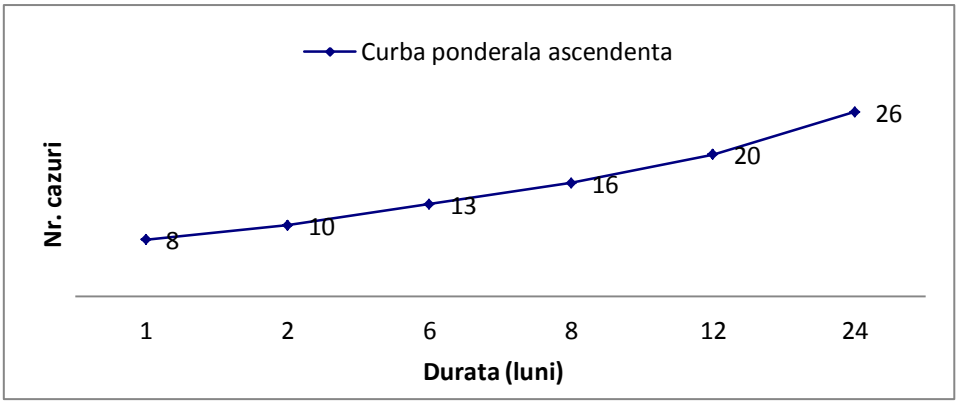

Fig. 2. Aspectul curbei ponderale la pacienții cu vârsta sub 2 ani în timpul RFG

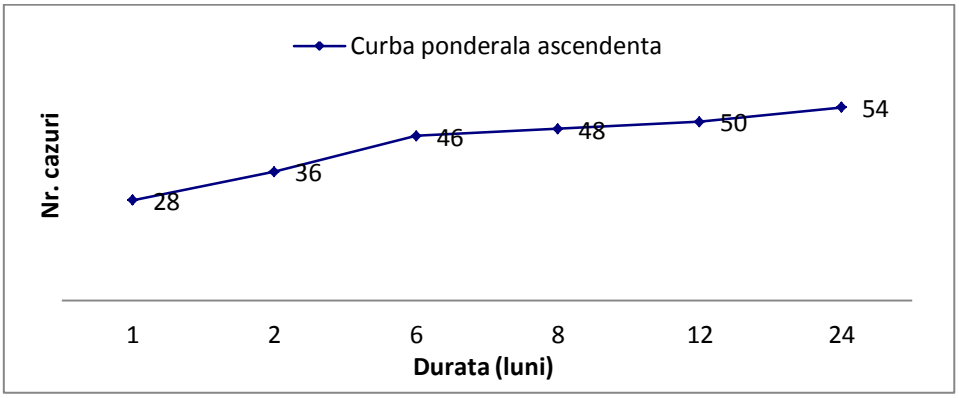

Fig. 3. Evoluția curbei ponderale sub RFG la pacienții cu vârsta peste 2 ani

Lotul II: în momentul diagnosticării BC hipotrofia ponderală a fost întâlnită la 81,82% din pacienți. După 8 luni de dietă fără gluten deficitul ponderal s-a menținut la 8 pacienți (14,63% din pacienți) (fig. 3).

În lotul II, după 24 luni de RFG deficitul ponderal a fost întâlnit în 7,14% din cazuri (4 pacienți), reluarea anamnezei evidențiind faptul că principala cauză a deficitului ponderal a fost nerespectarea RFG. Urmărind evoluția curbei ponderale după 24 luni s-a observat că obezitatea (BMI>30) a fost întâlnită în 16,07% din cazuri (9 pacienți), iar excesul ponderal (BMI>25) la 28,57% din cazuri (16 pacienți).

2. Ancheta alimentară. Indiferent de vârsta pacienților ancheta alimentară a evidențiat creşterea aportului caloric printr-un exces de lipide şi carbohidrați în dietă. Mai mult, în lotul II s-a remarcat un aport scăzut al fibrelor, calciului, fierului în special în dieta adolescenților cu BC. Aceste dezechilibre nutriționale au fost observate în special la copiii de vârstă şcolară şi adolescenți. Astfel, la copiii de vârstă şcolară excesul ponderal şi obezitatea au fost mult mai frecvent întâlnite decât la copiii de vârstă mică.

3. **Investigarea metabolismului lipidic.** În lotul I: la debutul bolii hipocolesterolemia a fost întâlnită în 3 cazuri, hipercolesterolemia în 2 cazuri iar lipidele au

prezentat valori normale la toţi pacienţii cu vârsta sub 2 ani. După 2 ani de RFG 3 pacienţi au prezentat hipercolesterolemie cu valori normale ale lipidelor totale. Efectuarea lipidogramei la părinţi a evidenţiat hipercolesterolemia familială în 2 cazuri. În lotul II s-au remarcat valori moderat scăzute ale lipidelor doar în 11,59% din cazuri, iar hipocolesterolemia a fost întâlnită în 6 cazuri. Probabil absenţa modificărilor semnificative ale metabolismului lipidic datorită malabsorbţiei intestinale s-a datorat diagnosticului precoce a BC la copiii incluşi în studiu. Ulterior, monitorizarea periodică a parametrilor metabolismului lipidic a evidenţiat hipercolesterolemia la 12 pacienţi cu vârsta peste 10 ani (21,4% din cazuri). Toţi pacienţii cu hipercolesterolemie prezentau exces ponderal (4 cazuri) şi obezitate (8 cazuri). Anamneza a evidenţiat hipercolesterolemia familială (cel puţin unul dintre părinţi prezenta hipercolesterolemie) în 6 cazuri. Hipertrigliceridemia a fost întâlnită la 2 pacienţi, fiind familială în ambele cazuri. Doi dintre pacienţi erau cunoscuţi cu diabet zaharat tip I diagnosticat anterior stabilirii diagnosticului de BC.

DISCUŢII

La copiii diagnosticaţi cu BC RFG pe viaţă reprezintă singura opţiune terapeutică care permite rafacerea absorbţiei intestinale, precum şi prevenirea complicaţiilor. Odată cu refacerea vilozităţilor intestinale, refacerea absorbţiei principiilor nutritive determină creşterea în greutate, uneori până la exces ponderal şi obezitate în condiţiile nerespectării unei diete echilibrate în carbohidraţi, proteine şi lipide.

Menţinerea dietei fără gluten nu este uşoară, mai ales pentru pacienţii de vârstă şcolară. În funcţie de tipul de produse fără gluten consumate pot apărea efecte secundare cum ar fi excesul ponderal şi obezitatea datorită consumului excesiv de carbohidraţi şi lipide. Multe dintre produsele fără gluten au tendinţa de a fi bogate în carbohidraţi, lipide şi calorii şi un conţinut scăzut în fibre, vitamine şi fier (3). De exemplu, pastele cu gluten conţin 41 grame de carbohidraţi comparativ cu pastele fără gluten care conţin 46 grame carbohidraţi la 100 grame de paste. Astfel, de multe ori adoptarea RFG duce la creşterea în greutate şi perturbarea metabolismului lipidic pe termen lung la copil şi adolescent.

La pacienţii incluşi în studiu am observat că raţia alimentară a fost hiperproteică, hiperlipidică şi hipercalorică, probabil şi datorită grijei excesive a mamelor de a oferi copiilor diagnosticaţi cu BC o raţie alimentară zilnică care să asigure o creştere şi dezvoltare optimă, în condiţiile în care nu a fost posibilă consilierea acestor părinţi şi copii de către un dietetician specializat pe probleme de nutriţie pediatrică. În studiul realizat în Italia de către Mariani et al (4) s-a observat că 72% dintre adolescenţii cu BC care au aderat strict la RFG au prezentat exces ponderal secundar unei diete bogată în lipide şi proteine şi săracă în carbohidraţi, fier, calciu şi fibre.

În prezent, obezitatea reprezintă o importantă problemă de sănătate publică la nivel mondial, prin prevalenţa în continuă creştere şi prin complicaţiile sale pe termen lung (dislipidemia, diabetul zaharat de tip II, hipertensiunea arterială) (5). Astfel, în studiul realizat de Venkatasubramani N. et al (2) s-a arătat că prevalenţa obezităţii la copiii şi adolescenţii din Statele Unite a crescut îngrijorător, 1 din 3 copiii fiind cu exces ponderal, iar 15% dintre aceştia vor deveni obezi (5).

În studiul de faţă excesul ponderal şi obezitatea în timpul dietei fără gluten au

predominat la pacienții de vârstă şcolară şi adolescenți şi au fost întâlnite la 28,57%, respectiv 16,07% dintre pacienții cu BC. De asemenea, este binecunoscut în prezent faptul că obezitatea poate fi una din formele atipice de debut a BC, de aceea screeningul imunologic trebuie efectuat inclusiv la copiii obezi (2).

Evaluarea profilului lipidic a arătat că la pacienții cu hipercolesterolemie familială valorile colesterolului au crescut mult mai repede comparativ cu cei fără antecedente familiale de dislipidemie în timpul RFG, indiferent de vârsta pacientului. 12 pacienți din cei cu obezitate şi exces ponderal au prezentat hipercolesterolemie. Ancheta nutrițională la aceşti pacienți a demonstrat o dietă inadecvată vârstei, datorată pe de o parte hiperprotecției materne (dorința mamelor de a corecta deficitele nutriționale prin diete hipercalorice, hiperlipidice) şi lipsei de consiliere nutrițională specializate şi, pe de altă parte, consumului de către pacienți a produselor fără gluten care sunt hipercalorice. Refacerea structurii şi funcțiilor enterocitului în timpul RFG determină creşterea absorbției trigliceridelor şi producția de lipo- şi apolipo-proteine, crescând riscul apariției dislipidemiei în condițiile unui aport nutrițional inadecvat.

O atenție deosebită trebuie acordată regimului fără gluten la pacienții cu diabet zaharat de tip I în vederea asigurării unui status nutrițional optim şi prevenirii complicațiilor pe termen lung (6,7,8).

CONCLUZII

Ancheta alimentară a copiilor cu BC incluşi în studiu a evidențiat că 44,64% dintre aceştia primeau o dietă săracă în fibre alimentare şi carbohidrați. Excesul ponderal şi obezitatea în timpul RFG au predominat la pacienții de vârstă şcolară şi adolescenți. RFG reprezintă singura metodă de tratament a BC şi trebuie să asigure un aport zilnic echilibrat caloric, lipidic şi proteic pentru a asigura un status nutrițional optim şi a preveni complicațiile pe termen lung.

TUBERCULOSIS PLEURO-PERICARDITIS: SO MUCH FIBRIN! CASE REPORT (Abstract): A young man with thoracic pain and progressive dyspnea was hospitalized for a pleuro-pericarditis. Ultrasonography confirmed the presence of left pleural and pericardial effusion with a high amount of fibrin. With exudative characters and without macroscopic appearance of empyema, the left pleural effusion has reoccurred two days later during the diagnosis period. Bacteriological exams were repetitively negative. A malign etiology was excluded as no atypical cells in the pleural fluid were found. Adenosine deaminase level was not helpful for the diagnosis. The diagnosis was established through video assisted thoracoscopy pleural biopsy which identified pleural granulomas. This case illustrates the difficulty of a pleuro-pericarditis tuberculosis diagnosis. **Keywords**: PLEURISY, PERICARDITIS, TUBERCULOSIS, FIBRIN.

Tuberculosis remains a global health threat with more than 1.5 million victims each year (1). Tuberculous pleurisy is the main cause of pleural effusion in many countries and the most common form of extrapulmonary tuberculosis as well as (2). According to the World Health Organization Global Tuberculosis Report 2013, an estimated 8.6 million people developed tuberculosis (3). Tuberculous pleuropericarditis is more likely to occur in younger patients who are more immunocompetent (3). Although other disorders including fungal diseases, sarcoidosis, tularemia and rheumatoid pleuritis may produce granulomatous pleuritis, more than 95% of patient with granulomatous pleuritis have tuberculosis (3). A high amount of fibrin on thoracic ultrasound can be a highly suggestive imagistic diagnostic clue. It seems that tissue factor, an initiator of coagulation, is important for the generation of fibrin, which supports granuloma formation in tuberculosis (4).

CASE REPORT

A 43-year-old man with a history of chronic alcohol consumption and peptic ulcer was referred due to thoracic pain and progressive dyspnea. Chest radiography revealed a massive left pleural effusion (fig. 1A). The electrocardiogram raised the suspicion of coexistent pericardial effusion (fig. 1B).

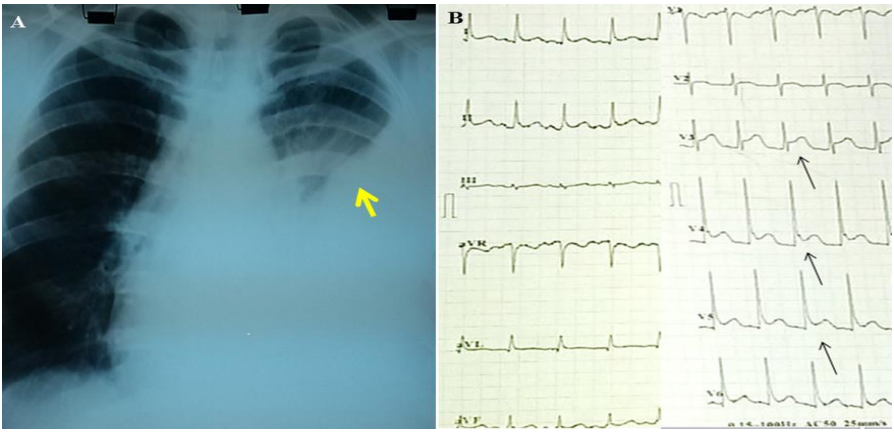

Fig. 1. The chest radiography and the electrocardiogram. Chest radiography demonstrating massive left pleural effusion (image A). The electrocardiogram shows diffuse ST segment elevation (image B).

Transthoracic echocardiography confirmed the presence of a moderate pericarditis, without hemodynamic consequences (fig. 2A). A high amount of fibrin was seen on the visceral pericardium. The echocardiogram showed also that the left visceral and parietal pleura were linked by many thick strings of fibrin (fig. 2 B). Thoracic ultrasound confirms that left visceral and parietal pleura are related by thick strings of fibrin (image B).

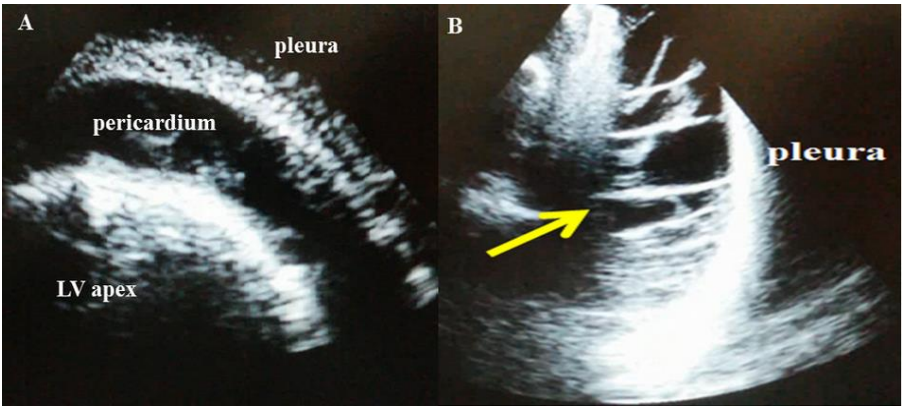

Fig. 2. Transthoracic echocardiography on apical four chambers view shows the presence of high amount of fibrin on the visceral pericardium (image A) and visceral pleura (image B).

Two liters of pleural effusion with exudate character were evacuated. After two days the pleural effusion has reoccurred. No atypical cells in the pleural fluid were found and bacteriological exams were negative. Human immunodeficiency virus test was negative. Adenosine deaminase level (57 U/L) was not helpful for the

diagnosis; usually a value of >70U/L means probably tuberculous pleurisy. Macroscopic examination of pleura by video assisted thoracoscopy confirmed thick fibrin strings between the visceral and parietal pleura (fig. 3A) and visualized multiple granulomas on the visceral pleura (fig. 3B).

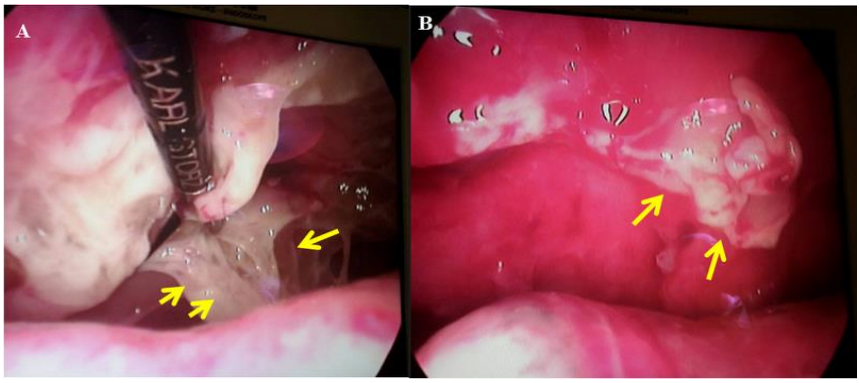

Fig. 3. Video assisted thoracoscopy shows thick fibrin formations between the left visceral and parietal pleura (image A) and the presence of granulomas on visceral pleura (image B).

Empiric tuberculosis treatment with chemotherapy was started after the second evacuation of pleural effusion, without reoccurrence of the pleural effusion in the following three days. Resected pleural granulomas (fig. 4A) were analyzed by pathologist and histologic examination confirmed their tubercular etiology. On histopathological investigation there were caseous granuloma and multinucleated Langhans giant cells with nuclei arranged in a horseshoe (fig. 4B). Thus, the etiology of pleuro-pericarditis was tuberculosis. The patient was discharged after 10 days in a good clinical condition. One year later the patient had no sign of relapse.

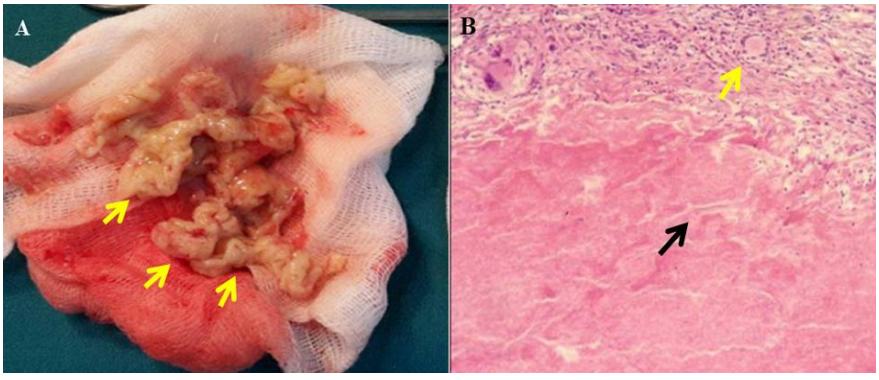

Fig. 4. Macroscopic and histopathology aspects of tuberculous granulomas. Macroscopic aspect after thoracoscopic excision (image A). Histopathology exam shows caseous granuloma (hematoxylin- eosin staining; 4x magnification) – black arrow; multinucleated Langhans giant cells with nuclei arranged in a horseshoe (hematoxylin - eosin staining; 40x magnification) – yellow arrow (image B).

DISCUSSION

Despite the introduction almost a century ago of a vaccine against *Mycobacterium tuberculosis*, tuberculosis remains a global health threat with more than 1.5 million victims each year (1). Tuberculous pleuro-pericarditis is more likely to occur in younger patients who are more immunocompetent (2). Mycobacterial antigens enter the pleural/pericardial space and interact with T-cells previously sensitized to mycobacteria, then results in a delayed hypersensitivity reaction. Although other disorders including fungal diseases, sarcoidosis, tularemia and rheumatoid pleuritis may produce granulomatous pleuritis, more than 95% of patient with granulomatous pleuritis have tuberculosis (2). A high amount of fibrin on thoracic ultrasound can be a highly suggestive imagistic diagnostic clue. It seems that tissue factor, an initiator of coagulation, is important for the generation of fibrin, which supports granuloma formation in tuberculosis (3). Tuberculous pleuro-pericarditis' diagnosis is not so easy. Multimodality imaging including thoracic ultrasound is very important. Algorithmic approach for tuberculous pleurisy diagnosing proposed by Doosoo J could be helpful (2). Nowadays it seems that SERS spectra and chemometric methods are new tool for tuberculosis determination (5).

CONCLUSIONS

This case illustrates that tuberculous pleuro-pericarditis' diagnosis sometimes is not so easy. Multimodality imaging including thoracic and cardiac ultrasound and video assisted thoracoscopy is very important. In this case histopathologic examination of resected pleural granulomas established the diagnosis.

ONCOLOGICAL EMERGENCIES IN THE EMERGENCY DEPARTMENT (Abstract): **Aims**: to assess the profile and the characteristic of oncological patients, establishing management in patients with neoplasia presented in the emergency department (ED), the analysis of short-term movements in patients with neoplasia whilst in the ED. **Material and Methods**: we performed a retrospective study on non-randomized consecutive cases. The lot analysis included 1315 oncological patients admitted in the Emergency Department of the Clinical Emergency Hospital "St. Spiridon" Iasi, in the period June 1st, 2009 - May 31st, 2010. 23.12% of the patients had high suspicion of neoplasia at the first visit to the ED. **Results**: 67.07% of patients were in metastatic stage disease located as follows: liver metastasis 37.59%, lung metastasis 18.36%, lymph node metastasis 13, 29%. After processing the data there were found statistically significant correlations between the age distribution of patients and the documented / suspected diagnosis of neoplasia ($p = 0.01$) in the sense that a neoplasia diagnosis in emergency was more frequent on people of young age. It should be mentioned that other studies rarely mention first diagnosis of neoplasia in emergency department with presence of complications. **Conclusion**: 1315 oncological patients presented in ED, almost a quarter of which presented high suspicion of neoplasia (still without histopathological confirmation) when in ED (23.12%). Most of them were aged male patients (over 65 years old), with tumors in the digestive system. A significant proportion (almost 60%) of these patients ended up in emergency due to complications and the therapy intended life support and pain management. Some of these patients were directed to further exploring and emergency outpatient therapy while 75% of patients were hospitalized after stabilization. Although we expected that the frequency of complications to be higher in patients previously diagnosed with cancer, data analysis showed no statistically significant differences ($p = NS$) between the rate of complications in patients previously diagnosed with neoplasia and those with high suspicion neoplasia first diagnosed in the ED.
Key words: ONCOLOGICAL EMERGENCIES, NEOPLASIA, EMERGENCY DEPARTMENT, METASTATIC STAGE DISEASE

Urgenţele oncologice sunt condiţii comune asociate cu o morbiditate şi mortalitate semnificative. Acestea pot fi definite ca şi condiţie acută cauzată de neoplazie sau tratamentul implicat, care necesită intervenţie rapidă pentru a evita apariţia complicaţiilor sau decesul (1).

În decursul anilor terapia antineoplazică a îmbunătăţit supravieţuirea pacienţilor cu neoplazii, diagnosticul prompt şi controlul urgenţelor oncologice ocupând un loc important. Din fericire, multe din aceste urgenţe (în special cele metabolice) pot fi prevenite cu succes dacă sunt suspicionate pe baza evoluţiei pacientului postterapie oncologică (2).

Îngrijirea pacienţilor cu urgenţe oncologice reprezintă o provocare nu numai pentru medicii oncologi, dar, de asemenea şi pentru medicii de medicină de urgenţă, existând mai multe tipuri de probleme medicale pentru care pacienţii cu neoplazie necesită asistenţă imediată în departamentul de urgenţă (insuficienţă respiratorie acută, sindroame ocluzive, hemoragie, anemie, durere, icter) (1).

O evaluare corespunzătoare este esenţială pentru majoritatea pacienţilor cu urgenţe de natură oncologică, important fiind de recunoscut şi tratat complicaţiile asociate cu neoplazia. Atenţia trebuie îndreptată pe acele probleme care ameninţă organele vitale sau compromit calitatea vieţii pe termen lung. Deseori, înainte de terapia definitivă prescrisă de oncolog, medicul de urgenţă trebuie sa stabilizeze aceşti pacienţi (3,4).

Pacienţii se pot prezenta în departamentul de urgenţă pentru efectele locale ale tumorii, efectele tratamentului oncologic sau pentru o problemă survenită independent de diagnosticul oncologic (1).

Urgenţele oncologice sunt clasificate astfel (1,3,4):

1. Urgenţe determinate de formaţiunile tumorale expansive;
2. Urgenţe metabolice;
3. Urgenţe determinate de tulburări sangvine şi de coagulare.

Având în vedere creşterea numărului de pacienţi prezentaţi zilnic în departamentul de urgenţă pentru diverse complicaţii ale unei patologii oncologice sau cu o simptomatologie de urgenţă (durere, greaţă, vărsături, febră, astenie marcată, pierderea stării de conştienţă) care ulterior se dovedeşte a fi determinată de un proces neoplazic nediagnosticat anterior, ne-am propus să realizăm un studiu referitor la urgenţele oncologice în Unitatea de Primire Urgenţe.

OBIECTIVE

Obiectivele studiului au fost:

- evaluarea profilului şi caracteristicilor pacienţilor oncologici,
- stabilirea managementului la pacienţii cu neoplazie prezentaţi în departamentul de urgenţă,
- analiza evoluţiei pe termen scurt a pacienţilor cu neoplazii în timpul staţionării în urgenţă.

MATERIAL ŞI METODĂ

Am realizat un studiu retrospectiv, pe cazuri consecutive, nerandomizat. Studiul a fost avizat de comisia de etică a spitalului.

Metoda de selecţie

Lotul analizat a inclus 1315 pacienţi oncologici primiţi în Departamentul de Urgenţă (Unitatea Primire Urgenţe) a Spitalului Clinic Judeţean de Urgenţă „Sf. Spiridon” din Iaşi în perioada 01 iunie 2009 – 31 mai 2010.

Criteriile de selecţie pentru pacienţii incluşi în studiu au fost următoarele:

- pacienți cu vârsta peste 18 ani, admişi în Unitatea Primire Urgențe a Spitalului "Sf. Spiridon" în perioada 1 iunie 2009 – 31 mai 2010.

- diagnostic cunoscut de neoplazie, aflat în evidența Clinicii Oncologice a Spitalului "Sf. Spiridon" Iaşi.

- suspiciune diagnostică de neoplazie pe criterii clinice sau paraclinice in Unitatea Primire Urgențe.

Metoda de achiziție a informațiilor

Am realizat analiza fişelor de urgență la pacienții incluşi în studiu, pacienți cu vârsta medie 63,5+/-13,81 ani. Datele au fost înscrise inițial într-un tabel *Microsoft Excel* şi analizate cu ajutorul programului *SPSS 18.0*. Etapele analizei statistice au fost: 1. Statistica descriptivă, 2. Corelațiile statistice.

REZULTATE ŞI DISCUȚII

Dintr-un total de 40322 prezentări în departamentul de urgență în perioada iunie 2009 – mai 2010, 1315 pacienți s-au prezentat pentru o patologie de natură oncologică.

Media de vârstă în lotul de studiu a fost de 63,5+/-13,81 ani, grupa de vârstă cea mai frecventă în cadrul pacienților incluşi în studiu a fost cea de peste 60 ani, respectiv 61,98 %, urmată de grupa pacienților cu vârsta cuprinsă între 40 – 60 ani, (33,40 %). Un procent de 5,62 % dintre pacienții incluşi în studiu au reprezentat grupa de vârstă tânără, respectiv 18 – 40 ani (fig. 1, fig. 2).

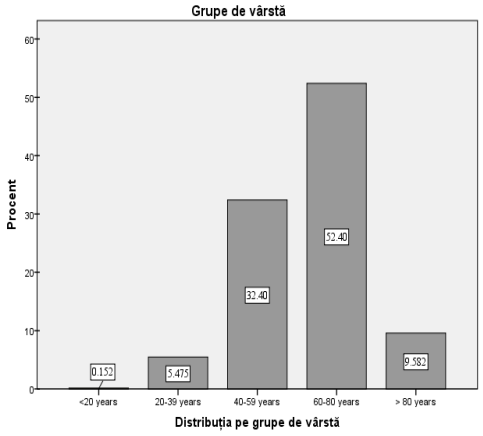

Fig. 1. Distribuția pacienților pe grupe de vârstă

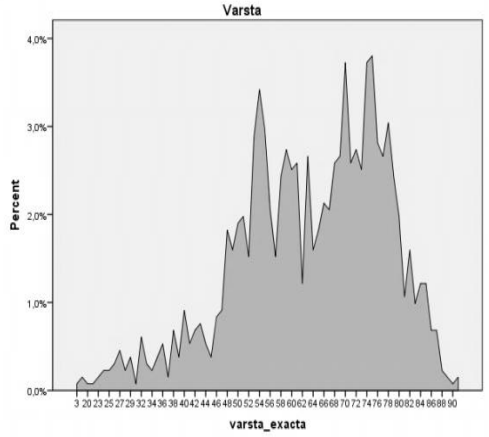

Fig. 2. Distribuția pacienților în funcție de vârstă

Trebuie să reținem că în lotul de studiu a existat o predispoziție a sexului masculin indiferent de grupa de vârstă (fig. 3). În perioada studiului 76,80 % dintre pacienți aveau precizat anterior diagnosticul de neoplazie, în timp ce 23,12 % dintre pacienți au prezentat suspiciune înaltă de neoplazie la prima vizită în departamentul de urgență (fig. 4).

Cele mai frecvente localizări ale neoplaziei în cadrul pacienților incluşi în studiu au fost reprezentate de: tub digestiv 29,03 %, leucemie/limfom 17,80 %, aparat genito-urinar 11,23 % şi sân 9,01 % (fig. 5).

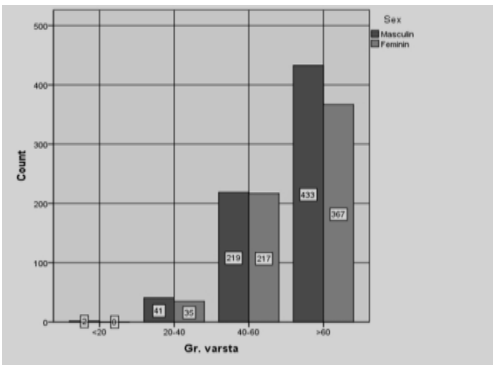

Fig. 3. Distribuția cazurilor funcție de sex şi grupă de vârstă

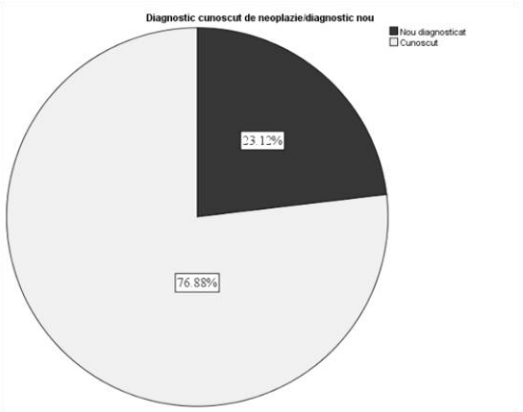

Fig. 4. Diagnostic cunoscut de neoplazie/diagnostic nou

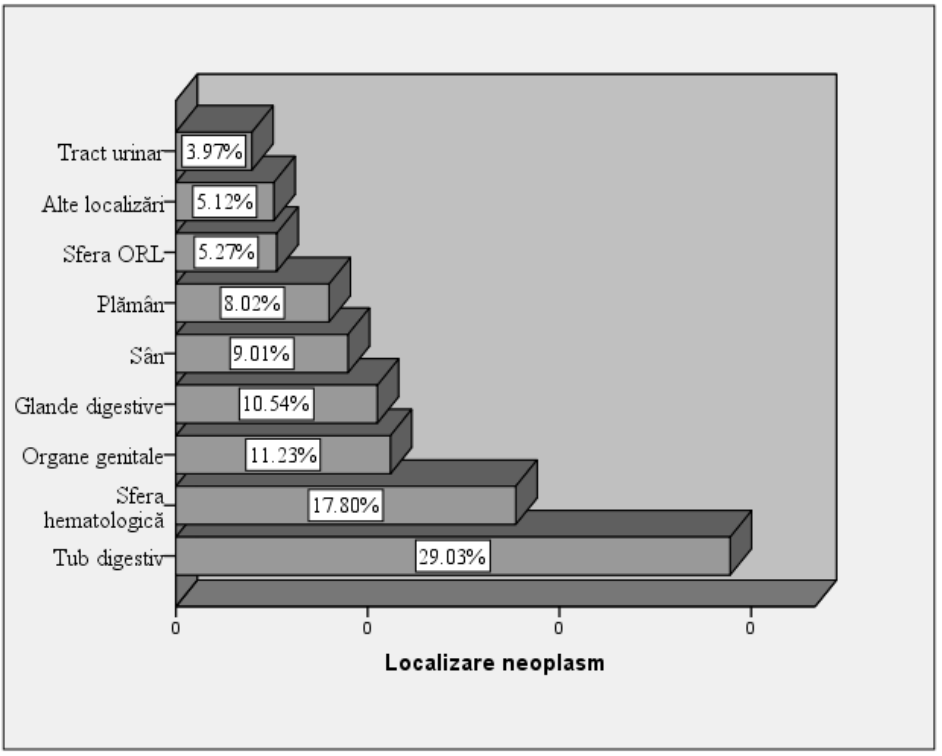

Fig. 5. Localizarea tumorilor

În lotul de studiu, 67,07 % dintre pacienți se aflau în stadiul de metastazare a bolii, cele mai frecvente localizări fiind reprezentate de: metastaze hepatice 37,59 %, metastaze pulmonare 18,36 %, metastaze ganglionare 13,29 % (fig. 6).

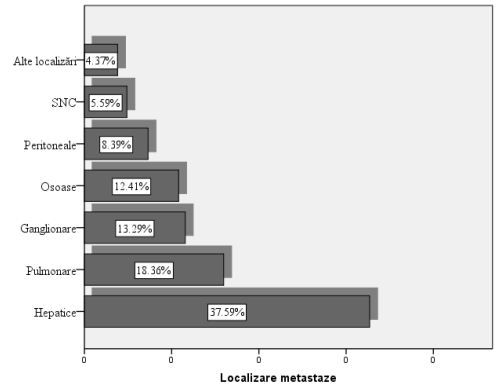

Fig. 6. Localizare metastaze

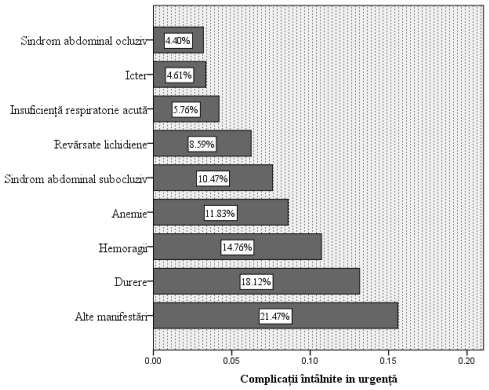

Fig. 7. Tipul complicațiilor în urgență

Din totalul pacienților prezentați în departamentul de urgență pentru o patologie oncologică, 59,92 % s-au prezentat pentru complicații date, fie de neoplazie, fie de tratamentul antineoplazic administrat. Cele mai frecvente complicații specifice au fost reprezentate de: sindroame hiperalgice (18,12 %), sindroame hemoragice (14,76 % - hemoragie digestivă superioară), sindroame anemice (11,83 %), sindroame subocluzive (10,47 %) (fig. 7).

Mortalitatea pacienților în departamentul de urgență (ceea ce semnifică un interval de maximum 24 h) este foarte redusă, respectiv 1,06 %, majoritatea pacienților fiind monitorizați şi tratați în urgență şi apoi internați în secțiile clinice de profil: oncologie şi hematologie (54,19 %), gastroenterologie (15,53 %) şi chirurgie generală (6,85 %) sau au putut merge la domiciliu cu recomandări terapeutice (23,44 %) (fig. 8).

Măsurile terapeutice în Unitatea Primire Urgențe au fost centrate pe susținerea funcțiilor vitale: oxigenoterapie, hidratare, montarea cateterelor venoase centrale, sonde urinare, sonde de aspirație naso-gastrică sau clisme evacuatorii. 23,44 %, respectiv 308 dintre pacienți au beneficiat de tratament activ în departamentul de urgență, principala acuză fiind durerea acută (6,4 % dintre pacienți au necesitat tratament analgetic de tip opioid).

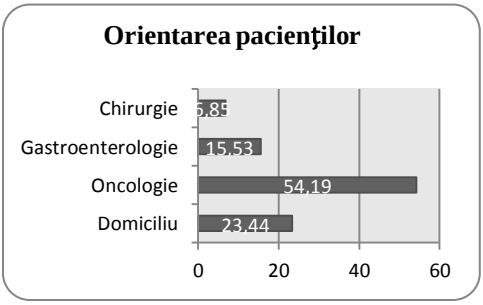

Fig. 8. Orientarea pacienților cu neoplazii din Unitatea Primire Urgențe

După prelucrarea datelor, au rezultat corelații statistic semnificative în ceea ce privește grupa de vârstă a pacienților din lotul de studiu şi diagnosticul cunoscut/suspectat de neoplazie (p= 0,01) (fig. 9) ceea ce semnifică diagnosticarea unei neoplazii în urgență mai frecvent la persoanele de vârstă tânără.

Deşi ne-am fi aşteptat ca frecvența complicațiilor să fie mai mare la pacienții diagnosticați anterior cu neoplazii, analiza

datelor nu arată diferenţe semnificative statistic (p=NS) între rata de apariţie a complicaţiilor la pacienţii diagnosticaţi anterior cu neoplazie faţă de cei cu suspiciune înaltă de neoplazie diagnosticaţi pentru prima dată în departamentul de urgenţă (fig.10). Este o realitate întâlnită în puţine alte studii realizate în acest domeniu, aceea că primul diagnostic de neoplazie este precizat în departamentul de urgenţă în prezenţa complicaţiilor, în condiţiile numărului redus al programelor de *screening*.

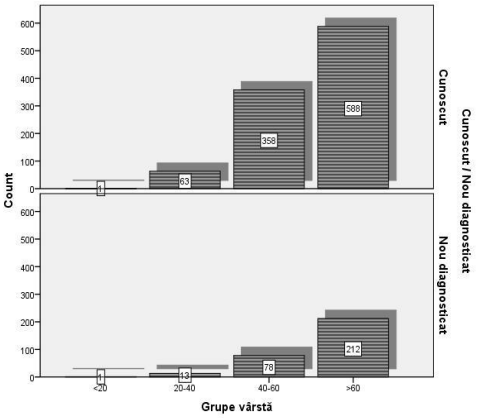

Fig. 9. Corelaţia grupă de vârstă - diagnostic

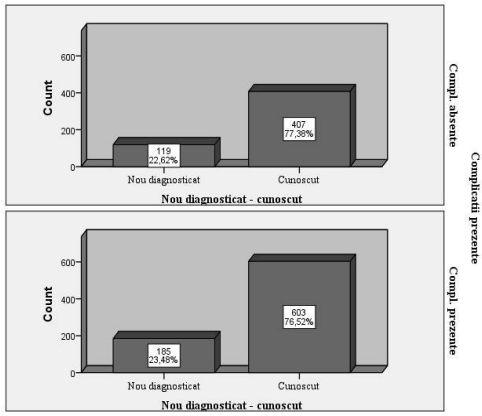

Fig.10. Corelaţia diagnostic nou/cunoscut - complicaţii

Pornind de la rezultatele studiului retrospectiv de faţă ne propunem aplicarea în practică a conceptului de *terapie de paleaţie în medicina de urgenţă după modelul din unele state din SUA şi Marea Britanie (Division of Palliative Emergency Medicine) (5), cu scopul îmbunătăţirii calităţii îngrijirilor acordate pacienţilor cu neoplazii prezentaţi în urgenţă, odată cu scăderea mortalităţii pe termen scurt şi îmbunătăţirea calităţii vieţii acestor pacienţi.*

CONCLUZII

Am inclus în studiul de faţă 1315 pacienţi oncologici prezentaţi în Unitatea Primire Urgenţe în decursul unui an, dintre care 23,12 % cu suspiciune înaltă de neoplazie (fără a avea încă confirmarea histopatologică) la prezentarea în urgenţă. Predomină pacienţii vârstnici (peste 65 de ani), de sex masculin, cu tumori la nivelul aparatului digestiv. Un procent important (aproape 60 %) dintre aceşti pacienţi ajunge în urgenţă datorită complicaţiilor, iar terapia vizează rezolvarea acestora, susţinerea funcţiilor vitale şi tratarea durerii. O parte dintre aceşti pacienţi sunt rezolvaţi în urgenţă, continuînd explorările şi terapia în ambulatoriu, în timp ce 75 % dintre pacienţi se internează după stabilizare. Rolul Departamentului de Urgenţă în evaluarea şi tratarea pacienţilor cu neoplazii este unul puţin evidenţiat de literatura de specialitate, dar totuşi trebuie recunoscută importanţa lui atât în diagnosticul iniţial cât mai ales pentru rezolvarea complicaţiilor şi susţinerea funcţiilor vitale.

NOUTĂȚI

DEMONSTRAREA ROLULUI LEUCOCIDINEI PANTON VALENTINE ÎN EVOLUȚIA INFECȚIILOR CUTANATE DETERMINATE DE *S. AUREUS*

În ciuda datelor epidemiologice care asociază infecțiile cutanate necrotizante cu producerea leucocidinei Panton Valentine (PVL), implicarea acestei toxine în virulența *S. aureus* a fost mult disputată datorită rezultatelor neconcludente ale studiilor *in vivo*. Cu toate acestea, majoritatea rezultatelor anterioare proveneau din experimente pe şoarece, specie la care neutrofilele, principalele ținte celulare ale PVL, sunt lipsite de sensibilitate la acțiunea acestei leucocidine. În contrast, neutrofilele de iepure prezintă aceeaşi sensibilitate la acțiunea PVL ca şi celulele umane. Studiul realizat de Lipinska U *et al.* a utilizat iepurele drept model pentru infecția cutanată, în scopul evidențierii implicării PVL în patogenitatea *S. aureus*. Experimentul a arătat că iepurii care au fost injectați intradermic cu suspensii ale unor tulpini comunitare PVL pozitive de *S. aureus* au dezvoltat leziuni cutanate mai severe şi un grad mai mare de necroză tisulară comparativ cu tulpinile PVL negative şi au prezentat o creştere a titrului anticorpilor anti-LukS-PV. Acest studiu dovedeşte că iepurele este un model animal mai potrivit pentru investigarea rolului PVL în infecțiile stafilococice şi susține legătura stabilită pe criterii epidemiologice între tulpinile stafilococice PVL pozitive şi infecțiile cutanate necrotizante (Lipinska U, Hermans K, Meulemans L, Dumitrescu O, Badiou C, Duchateau L *et al*. Panton-Valentine Leukocidin Does Play a Role in the Early Stage of *Staphylococcus aureus* Skin Infections: A Rabbit Model. *PLoS One*. 2011; 6(8):22864).

3. Spitalul Clinic de Urgenţe pentru Copii " Sf. Maria", Iaşi, Secţia Hemato-Oncologie

DETECTION OF FUSION GENE - INTEGRANT PART OF THE ASSESSMENT OF CHILDREN WITH ACUTE LEUKEMIA (Abstract): Acute leukemia is the most common malignancy in children, being mostly produced by such chromosomal abnormalities as translocations or inversions causing gene fusion. Different clinical studies showed that translocations identified in ALL (acute lymphoblastic leukemia) and AML (acute myeloblastic leukemia) may be used to classify patients into risk groups. **Aim:** To detect three fusion genes that have been proven very important in patient classification: t(9:22)p190, t(4:11)and t(12:21). **Material and method**: We conducted a prospective study on 30 patients with acute leukemia diagnosed in the interval September 2009 - September 2010 at the Iasi Hemato-Oncology Unit of Saint Mary Hospital for Children. **Results**: We found t(9:22)p190 in two patients, t(4:11) in two patients and t(12:21) in one patient. From the total of 30 patients, 7 were considered at high-risk, 3 were diagnosed with AML, and 20 were considered at standard-risk. **Conclusions**: Day 33 can still be considered the reference time in the evaluation of treatment response; patients with BCR-ABL seem to have a worse prognosis than those who do not have this translocation. The detection of fusion genes is very important in patient classification. **Key words**: LEUKEMIA, CHILD, FUSION GENES

Leucemia acută este cea mai frecventă cauză de malignitate la copil, reprezentând 30% din cazurile de cancer în copilărie. O mare parte din leucemiile acute sunt produse de anomalii cromosomiale de tipul translocaţiilor sau inversiilor care produc gene de fuziune (1,2,3,4). Cele mai frecvente anomalii întâlnite în leucemiile acute la copii sunt t(9:22), t(4:11), t(15:17) şi inversia(16) (5, 6, 7). Numeroase studii clinice au arătat că translocaţiile din LAL (leucemia acută limfoblastică) şi LAM (leucemia acută mieloblastică) pot fi utilizate pentru ierarhizarea pacienţilor pe grupe de risc. De exemplu t(9:22) şi t(4:11) în LAL sunt asociate cu un prognostic nefavorabil iar t(12:21) în LAL şi t(8:21), t(15:17), inversia(16) în LAM sunt asociate cu prognostic favorabil (1,7,8,9). Punerea în evidenţă a acestor anomalii cromosomiale se poate realiza prin tehnici diferite, dintre care *nested RT-PCR* are una din cele mai bune rezoluţii(1).

MATERIAL ŞI METODĂ

Studiul de faţă a urmărit detecţia prezenţei genelor de fuziune la pacienţii inter-

naţi în Secţia Hemato-Oncologie a Spitalului Clinic de Urgenţe pentru Copii "Sf. Maria", Iaşi şi s-a desfăşurat pe o perioadă de un an (octombrie 2009-septembrie 2010), fiind un studiu de tip prospectiv.

Criteriile de includere în studiu au fost:

- pacienţi cu vârsta sub 18 ani
- pacienţi cu diagnosticul de leucemie acută confirmat prin medulogramă şi imunofenotipare
- pacienţi care au acceptat intrarea în studiu şi au semnat consimţământul informat (consimţământul a fost semnat de aparţinători, iar în cazul pacienţilor adolescenţi, aceştia au semnat şi ei un consimţământ în afara celui semnat de părinţi)

Obiectivele au constat în identificarea prezenţei genelor de fuziune la aceşti pacienţi şi realizarea de corelaţii între tipul genei de fuziune, imunofenotip, vârsta pacienţilor şi răspunsul la tratament.

În perioada 1 octombrie 2009 - 1 septembrie 2010 au fost diagnosticaţi cu leucemie acută, în secţia de Hemato-Oncologie a Spitalului "Sf. Maria", Iaşi, un număr de 30 de copii cu vârste cuprinse între 27 de zile şi 16 ani. Diagnosticul a fost stabilit pe baza manifestărilor clinice şi a rezultatelor analizelor paraclinice (hemogramă, medulogramă, imunofenotipare). Ulterior, pacienţii confirmaţi cu diagnosticul de leucemie acută au fost testaţi pentru prezenţa genelor de fuziune prin RT-PCR. Testarea a fost efectuată la diagnostic pentru toţi pacienţii, în ziua 33 de tratament pentru 10 pacienţi şi în ziua 56 pentru 2 pacienţi.

REZULTATE ŞI DISCUŢII

Împărţirea pacienţilor pe grupe de risc este de o deosebită importanţă pentru instituirea tratamentului deoarece în funcţie de acestea pacienţilor respectivi li se aplică un anumit tip de protocol chimioterapic mai simplu sau mai complex. Ierarhizarea pacienţilor se face pe baza unor criterii clinice şi paraclinice: vârstă, hemograma la diagnostic, imunofenotip, prezenţa sau absenţa unei translocaţii, răspunsul la corticoterapie (ziua 8) şi la chimioterapie (8).

Pacienţii din studiu au fost împărţiţi pe grupe de vârstă astfel: copii sub 2 ani (4 pacienţi), copii cu vârsta între 2 şi 10 ani (12 pacienţi), copii peste 10 ani (11 pacienţi). Prima grupă de vârstă este considerată a fi de risc crescut cu un prognostic mult nefavorabil pentru nou-născuţi, a II-a grupă are prognostic bun din acest punct de vedere, iar copiii cu vârsta peste 10 ani au, de asemeni un prognostic nefavorabil. Cele mai frecvente manifestări clinice au fost: astenia fizică, inapetenţa şi durerile osoase. Adenopatiile au fost obiectivate la 19 pacienţi, hepatosplenomegalia la 23, paloarea la 25 dintre pacienţi, scăderea ponderală la 22 dintre pacienţi.

Au fost diagnosticaţi 2 pacienţi care prezintă şi Sindrom Down, însă asocierea acestei patologii nu implică un prognostic nefavorabil pentru răspunsul la tratament.

Numărul de leucocite la diagnostic permite încadrarea leucemiilor acute în 3 forme – leucemică (număr de leucocite în limite normale), aleucemică (număr scăzut de globule albe), forma hiperleucocitară (globule albe>20.000 în hemograma la diagnostic).

Au prezentat formă hiperleucocitară considerată cu risc crescut, 7 pacienţi.

Medulograma a confirmat prezenţa de blaşti limfoizi sau mieloizi în măduva osoasă la toţi pacienţii incluşi în studiu.

În funcţie de imunofenotip, pacienţii au fost împărţiţi astfel: leucemie acută limfoblastică cu celule precursoare B 27 pacienţi, leucemie acută mieloblastică 3 paci-

enţi. Nici unul din pacienţi nu prezintă imunofenotip de celulă B matură considerat a avea prognostic rău. Imunofenotipul de celulă precursoare B este considerat a avea prognostic bun, cu atât mai bun cu cât stadiul de maturare al celulelor care formează clona malignă este mai precoce.

Răspunsul la tratament este un factor de prognostic foarte important în leucemiile acute. Acesta este cuantificat la ziua 8 – răspunsul la corticoterapie, pacientul fiind considerat că prezintă corticosensibilitate dacă nu mai prezintă blaşti în sângele periferic sau dacă numărul lor a scăzut şi corticorezistent dacă numărul de blaşti este acelaşi cu cel de la diagnostic sau mai mare.

Răspunsul la chimioterapie este cuantificat în ziua 33 (sfârşitul tratamentului de inducţie) prin medulogramă, chimiosensibilitatea fiind apreciată prin gradul remisiunii.

În lotul nostru 7 pacienţi au fost corticorezistenţi şi doar unul singur a fost şi chimiorezistent.

Încă de la diagnostic s-a urmărit identificarea prezenţei genelor de fuziune prin RT-PCR pentru o încadrare mai exactă a pacienţilor pe grupe de risc. Studiul de faţă şi-a propus detectarea a 3 gene de fuziune: t(9:22), t(4:11), t(12:21).

MLL-AF4 (*mixed lineage leukemia*) (t(4:11)) este întâlnită la 50-70% din leucemiile acute limfoblastice neonatale şi aproximativ 5% din cazurile de LAL la copilul mare şi adulţi. În cazul MLL-AF4 au fost identificate cel puţin 10 puncte de ruptură în interiorul genelor. La copilul mare prezenţa acestei gene se asociază cu prognostic nefavorabil şi reprezintă o indicaţie pentru transplantul medular. La nou-născuţii cu LAL este prezentă aproape obişnuit şi nu reprezintă o indicaţie de transplant. Studii recente au pus în evidenţă faptul că unele variante ale acestei gene se găsesc şi în populaţia normală ceea ce ar putea fi punctul de plecare pentru noi cercetări în domeniu (9,10,11).

În lotul nostru a fost identificată această genă la un singur caz - un nou născut diagnosticat la 27 de zile cu LAL.

BCR-ABL (*breackpoint cluster region*), care este o marcă pentru Leucemia mieloidă cronică, se întâlneşte şi în 5% din LAL la copil şi 20-50% din LAL la adulţi, incidenţa crescând cu vârsta. În LMC ruptura în BCR se face în "*major breackpoint cluster region*"(M-BCR), iar a 2-a zonă de ruptură în BCR (m-BCR) se găseşte aproape exclusiv în LAL cu cromosom Philadelphia+. Prezenţa cromosomului Philadephia în LAL este asociată cu un prognostic nefavorabil şi este, de asemeni, o indicaţie pentru transplant medular.

În lotul nostru au fost identificaţi doi pacienţi cu m-BCR. Unul din pacienţi prezenta o formă hipercelulară de LAL (GA= 250000/mmc) şi a decedat la 3 zile de la stabilirea diagnosticului. Celălalt pacient prezintă o formă rară de LAL cu debut prin tumefacţie osoasă dureroasă (rezultatul de la examenul anatomo-patologic al biopsiei osoase a sugerat diagnosticul). Acest copil a prezentat corticorezistenţă în ziua 8 de tratament şi chimiorezistenţă în ziua 33, prognosticul fiind extrem de rezervat.

TEL-AML1 (ETV6-RUNX1) este cea mai frecventă anomalie din LAL la copil, incidenţa fiind de 25%. Majoritatea pacienţilor sunt încadraţi în grupul de vârstă 1-12 ani cu un vârf între 2-5 ani. Unele studii au raportat prognostice favorabile pentru pacienţii pozitivi pentru TEL-AML1.

În lotul nostru a fost identificat un singur pacient cu această translocaţie, acesta având vârsta de 4 ani.

Pacienţii la care nu s-a detectat prezenţa nici unei gene de fuziune au fost încadraţi

pe grupe de risc în funcţie de celelalte criterii: vârsta la diagnostic, numărul iniţial de leucocite, imunofenotip şi răspunsul la tratament (corticoterapie şi chimioterapie) (14, 15, 16). Astfel pacienţii cu BCR-ABL pozitiv au fost încadraţi în grupul de risc înalt, la fel pacienţii cu forme hiperleucocitare şi cei care au prezentat corticorezistenţă în ziua 8. În total 7 pacienţi au fost încadraţi în grupul cu risc înalt, 3 pacienţi au fost diagnosticaţi cu LAM, 20 pacienţi au fost încadraţi in grupul de risc standard. Din numărul total de 30 de pacienţi diagnosticaţi 2 pacienţi au decedat, iar 10 sunt pierduţi din evidenţă, 2 pacienţi au plecat chiar după momentul diagnosticului, ceilalţi la finalul tratamentului de inducţie, fie pentru tratament în centre din străinătate, fie au renunţat la tratament.

Pacienţii urmează tratament conform protocolului ALL-IC-BFM 2002, urmându-se aceleaşi momente de investigare a răspunsului la tratament: ziua 33 şi ziua 56.

CONCLUZII

Ziua 33 rămâne un moment de referinţă în evaluarea răspunsului la tratament cu posibilitatea emiterii unor previziuni prognostice.

S-a confirmat valoarea de factor prognostic de risc înalt a prezenţei genei de fuziune BCR-ABL, evoluţia pacienţilor fiind nefavorabilă soldându-se într-unul din cazuri cu deces.

Detecţia genelor de fuziune este foarte importantă în stratificarea pacienţilor pe grupe de risc.

Mulţumiri

Acest studiu a fost finanţat de Universitatea de Medicină şi Farmacie „Gr. T. Popa”, Iaşi, prin grantul intern, contract nr. **16842/30.09.2010** cu titlul: ELABORAREA UNUI MODEL INTEGRAT DE EVALUARE A PACIENTILOR COPII CU LEUCEMIE ACUTA PRIN UTILIZAREA RT-PCR PENTRU GENE DE FUZIUNE

NOUTĂȚI

MARKERI DE ACTIVITATEA A NEFRITEI LUPICE LA COPIL

Schemele terapeutice curente folosite pentru copiii cu nefrită lupică (LN) sunt asociate cu efecte secundare şi toxocitate semnificative, in perioade vulnerabile ale creşterii şi dezvoltării. Numărul redus de biomarkeri, în special pentru copii, împiedică o îngrijire corespunzătoare şi dezvoltarea de noi strategii terapeutice. Autorii au analizat markerii sistemului imun (B-cell acitvating factor BAFF cunoscut şi ca TNF, RANTES), complementul (Bb,C1q, C3d-CIC, C5a) şi activarea celulelor endoteliale (sVCAM-1) la copiii cu LN (n=22, vârsta medie 14,8±4,7 ani), sindrom nefrotic (n= 13) şi un grup de control de vârstă comparabilă (n=20) pentru a identifica parametrii care corelează cu activitatea LN. Fragmentele de complement ale căii alternative (Bb, $p<0,0004$), clasice -C3d-CIC $p<0,0001$) şi a căii comune (C5a, $p < 0,0001$) sunt semnificativ crescute]n perioada de activitate comparativ cu cea de remisiune a LN. Activarea complementului a fost asociată cu apariţia de anticorpi anti-C1q şi scăderea complementului C1q. Fragmentele activatoarea a complementului se corelează foarte strâns cu markerii sistemului imun şi activarea celulelor endoteliale. Ansamblul acestor parametri pot avea o mare valoare în identificarea semnelor precoce de activitate sau de remisiune a LN la copii, ba mai mult, pot proba utilitatea în evalaurea noilor tratamente şi determinarea optimizării folosirii acestora. (Edelbauer M, Kshirsagar S, Riedl M, Haffner D et al, Markers of childhood lupus nephritis indicating disease activity, *Ped Nephrol*, 2011; 3(26): 401-410).

SENSITIZATION TO ASCARIS LUMBRICOIDES AND ASTHMA SEVERITY IN CHILDREN (Abstract)**:** There is little information concerning asthma severity and sensitization to *Ascaris lumbricoides* in pediatric patients. **Material and methods:** The relationship between sensitization to *Ascaris lumbricoides* and asthma severity in 219 patients with a high prevalence of parasitic exposure (IgE antibodies) was studied by using linear, multivariate and logistic regression. **Results**: Sensitization to *Ascaris lumbricoides* was associated with positive skin tests for aeroallergens, increased total serum IgE, increased eosinophils, reductions in FEV1 and FEV1/FVC ratio, increased airway Methacholine, bronchodilator responsiveness, and hospitalizations for asthma in the past year. **Conclusions:** Sensitization to *Ascaris lumbricoides* is associated with increased severity of asthma among Romanian children. This association is mediated by a high degree of atopy among the asthma children sensitized to *Ascaris lumbricoides* and belonging to a population with a low prevalence of helminthiasis.
Key words: *ASCARARIS LUMBRICOIDES*, ASTHMA, HELMINTHIASIS, ATOPY

Infecția cu *Ascaris lumbricoides* afectează la nivel mondial, aproximativ 1,4 miliarde de persoane, cu o distribuție preponderentă la populațiile cu un nivel socio-economic scăzut. Prevalența ascaridiozei în România a scăzut între 1953-1956 pe fondul ameliorării condițiilor igienico-sanitare şi accesibilității la tratamentul antihelmitic, iar începând cu 1997 înregistrează o creştere lentă, probabil, datorită alterării statusului socio-economic (1).

Relația dintre infestarea cu *Ascaris lumbricoides* şi astm, sau atopie este controversată, deşi este dovedit că totuşi se asociază cu un risc de atopie şi simptome astmatice în zonele cu prevalență ridicată a infestațiilor (2,3,4).

Aceste date susțin relația complexă dintre helmintiază, atopie şi astm, relație mediată de factori dependenți de gazdă, durata şi intensitatea infestației şi expunerea concomitentă la acțiunea altor paraziți (5,6,7).

În literatura de specialitate există puține informații privind corelația dintre *A. lumbricoides* şi severitatea astmului, în special

în zonele cu o prevalenţă scăzută a infestării cu helminţi (8,9).

În cadrul prezentului studiu am investigat asocierea dintre sensibilizarea la *A. lumbricoides* şi severitatea astmului pe un lot de 219 copii diagnosticaţi cu astm bronşic.

MATERIAL ŞI METODĂ

Studiul a fost efectuat pe un lot de 219 copii cu vârsta cuprinsă între 6-16 ani, diagnosticaţi cu astm, în perioada 2008-2010, în Spitalul Clinic de Urgenţă pentru copii "Sf. Maria" din Iaşi. Criteriile de includere în lot au fost reprezentate de prezenţa diagnosticului de astm sau istoric de crize de astm în cursul ultimelor 12 luni.

A fost determinată prezenţa anticorpilor IgE, numărul de eozinofile şi reactivitatea căilor respiratorii la Metacolină şi bronhodilatatoare. La 137 (62,5%) pacienţi au fost examinate materiile fecale pentru evidenţierea prezenţei unor paraziţi.

Probele ventilatorii şi răspunsul la bronhodilatatoare. Pacienţii au fost instruiţi să evite utilizarea de bronhodilatatoare cu durată scurtă de acţiune, timp de cel puţin 4 ore înaintea testării iar spirometria a fost efectuată cu pacientul în poziţie şezândă, după aplicarea unui clips nazal.

Cele mai mari valori au fost obţinute în cazul FEV_1 şi a capacităţii vitale forţate (FVC). După realizarea testării spirometrice în condiţii bazale, pacienţilor li s-au administrat două pufuri de Albuterol (200µg), iar testarea a fost repetată după 15 minute. Răspunsul la bronhodilatatoare a fost considerat prezent în cazul unei creşteri cu cel puţin 12% (200ml) a FEV_1 după administrarea de Albuterol.

Inducerea bronhoconstricţiei prin administrarea de Metacolină. După realizarea spirometriei bazale subiecţii a căror FEV_1 a fost de cel puţin 65% au fost supuşi testului de provocare cu Metacolină conform protocolului Chatham (5 inhalări de soluţie salină urmate de o inhalare de soluţie de Metacolină 1mg/ml, 1-4 inhalări de soluţie de Metacolină 5mg/ml şi o inhalare de soluţie de Metacolină 25 mg/ml). Fiecare inhalare a durat 6 secunde şi a fost urmată de 2 secunde de apnee. Testele spirometrice au fost repetate la 180, 210 şi 240 secunde după fiecare etapă de inhalare. Testarea a fost întreruptă în cazul scăderii FEV_1 cu cel puţin 20% din valoarea înregistrată după inhalarea soluţiei saline. Responsivitatea căilor respiratorii la inhalarea de Metacolină a fost considerată pozitivă în cazul scăderii cu 20% a FEV_1 la o doză de Metacolină $\leq$ 1,98 µmol.

Testarea cutanată a fost efectuată pe faţa ventrală a antebraţului folosind antigenele *Dermatophagoides pteronyssinus, Dermatophagoides farinae, Blatella germanica, Periplaneta americana, Alternaria tenuis*, păr de pisică şi de câine, polen mixt de ierburi şi de copaci. Testarea cutanată a fost considerată pozitivă în cazul apariţiei unei papule cu diametrul $\geq$ 3mm după stabilirea diametrului maxim al controlului negativ.

Concomitent s-a realizat şi examenul coproparazitologic în cadrul laboratorului Spitalului Clinic de Urgenţă pentru copii "Sf. Maria'' Iaşi.

Datele obţinute au fost analizate şi exprimate numeric, logaritmic şi binar, iar asocierile dintre diferiţi factori au fost interpretate cu ajutorul testelor de corelaţie. Prelucrarea statistică a fost realizată prin intermediul programului *Statistica 8.0*.

REZULTATE

Din totalul celor 219 pacienţi incluşi în studiu, 85 (38,8%) au prezentat sensibilizare la antigenele de *A. lumbricoides*. Majoritatea pacienţilor sensibilizaţi au fost de sex

masculin, au fost spitalizaţi pentru astm în timpul ultimului an, au prezentat cel puţin un test cutanat specific pozitiv, responsivitate crescută a căilor respiratorii la testarea cu Metacolină şi bronhodilatatoare comparativ cu pacienţii nesensibilizaţi (tab. I).

TABELUL I
Caracteristicile pacienţilor incluşi în studiu

Parametri evaluaţi	Sensibilizare la *A. lumbricoides*				p
	Nr	%	Nr	%	
Sex masculin	60	69,6	77	58,6	0,2
Nivelul educaţional al părinţilor					
Primare sau gimnaziale	44	50,9	58	43,7	0,33
Liceu	19	22,8	36	27,2	
Studii superioare	23	26,3	39	29,1	
Expunerea la fum de ţigară	22	25,7	35	26,3	0,91
Mamă astmatică	25	28,7	45	33,7	0,29
Tată astmatic	19	22,5	27	20,8	0,72
Teste cutanate pozitive la ≥ 1 alergen	81	95,3	106	79,8	<0,001
Responsivitate la testarea cu metacolină ≤ 1,98 μmol	54	70,4	72	58,3	0,02
Responsivitate la bronhodilatatoare	16	19,1	10	8,3	0,002
Spitalizare pentru astm în ultimul an	7	7,6	4	3,4	0,07
Prezentare în urgenţă pentru crize astmatice în ultimul an	67	84,2	106	79,1	0,21

În cazul pacienţilor sensibilizaţi la *A. lumbricoides* s-au înregistrat valori mai mari ale vârstei medii, ale IgE seric total, a numărului de eozinofile, a responsivităţii căilor respiratorii la bronhodilatatoare (exprimată sub forma diferenţei dintre valorile FEV_1 înainte şi după administrarea de bronhodilatatoare), a responsivităţii la testarea cu Metacolină şi valori mai mici ale raportului FEV_1/FVC comparativ cu pacienţii nesensibilizaţi. Nu au fost înregistrate diferenţe statistic semnificative în ceea ce priveşte nivelul educaţional al părinţilor şi istoricul matern sau patern de astm la pacienţii cu şi fără sensibilizare la antigenele de *A. lumbricoides*.

Reactivitatea cutanată la alergeni, IgE total, IgE specific şi numărul de eozinofile s-a evidenţiat prin rezultatele analizei bi şi multivariate ale relaţiei dintre sensibilizarea la *A. lumbricoides,* eozinofilie şi markerii alergiei. Sensibilizarea la *A .lumbricoides* a fost asociată cu o creştere de 5 ori a şanselor de a prezenta mai mult de un test cutanat pozitiv la alergeni şi de 3 ori a riscului de prezentare în urgenţă pentru crize astmatice. De asemenea, sensibilizarea la *A. lumbricoides* a antrenat o creştere moderată a riscului de hipereozinofilie şi a numărului total de teste cutanate pozitive.

Determinările spirometrice, responsivitatea căilor respiratorii la testarea cu bronhodilatatoare şi metacolină. Rezultatele analizei bi şi multivariate ale relaţiei dintre sensibilizarea la *A.lumbricoides,* indicatorii funcţiei pulmonare şi responsivitatea căilor aeriene la bronhodilatatoare şi metacolină a dovedit că sensibilizarea la *A. lumbricoides* a antrenat o creştere de 1,6 ori a şanselor de bronhoconstricţie semnifi-

cativă după inhalarea de Metacolină şi de 2,6 ori a şanselor de bronhodilatație semnificativă după administrarea de Albuterol. Similar, sensibilizarea la *A. lumbricoides* s-a asociat semnificativ cu o reducere a FEV_1 şi nesemnificativ cu reducerea raportului FEV_1/FVC (tab. II).

Exacerbarea astmului. S-a dovedit că sensibilizarea la *A. lumbricoides* antrenează exacerbarea astmului cu o creştere de 1,4 ori a şanselor de prezentare în urgență pentru crize de astm şi de 2,4 ori a riscului de spitalizare pentru astm, rezultatul nefiind influențat semnificativ prin eliminarea factorilor vârstă, apartenența la sex şi nivelul educațional parental.

TABELUL II

Relația dintre sensibilizarea la *A. lumbricoides* şi severitatea astmului

Teste	Neajustat	p	Ajustare pentru vârstă, sex, nivel educațional parental	p
Teste cutanate pozitive la ≥ 1 antigen	5,13 (2,38-11,09)	< 0,001	5,15 (2,36-11,21)	< 0,001
Responsivitatea căilor respiratorii la ≤ 1,98 μmol de Metacolină	1,70 (1,11-2,62)	0,016	1,61 (1,02-2,54)	0,040
Responsivitate la bronhodilatatoare	2,60 (1,44-4,69)	0,002	2,60 (1,34-5,05)	0,005
Prezentare în urgență pentru crize de astm în ultimul an	1,41 (0,85-2,34)	0,184	1,53 (0,91-2,58)	0,110
Spitalizare pentru astm în ultimul an	2,37 (0,99-5,67)	0,053	3,08 (1,23-7,68)	0,016

DISCUȚII

Cercetările au stabilit că sensibilizarea la *A. lumbricoides* s-a asociat cu inducerea reacției alergice, hipereozinofilie, niveluri crescute de IgE total şi specific, responsivitate crescută la bronhodilatatoare, reducerea funcției pulmonare şi spitalizarea pentru astm. Asocierea dintre sensibilizarea la *A. lumbricoides* şi indicatorii severității astmului este mediată de o creştere a gradului de atopie în rândul copiilor sensibilizați la *A. lumbricoides*. Exacerbarea răspunsului imun la antigenele *A. lumbricoides* în cazul copiilor cu astm şi atopie severă poate constitui o explicație plauzibilă şi asigură protecția împotriva infestației cu acest parazit.

Reactivitatea încrucişată, evaluată individual, nu poate explica în totalitate rezultatele prezentului studiu deoarece 56,8% dintre subiecții care au avut cel puțin un test cutanat pozitiv şi o parte dintre pacienții cu IgE specifice prezente, nu au fost sensibilizați la *A. lumbricoides*. Mai mult decât atât, 12,9% dintre copii cu teste cutanate negative la alergenii aerieni au fost sensibilizați la *A. lumbricoides* ceea ce sugerează că deşi majoritatea copiilor sensibilizați la *A. lumbricoides* sunt atopici, sensibilizarea la *A. lumbricoides* poate apare şi în absența acesteia la alergenii aerieni comuni. O explicație alternativă a rezultatelor prezentului studiu o constituie pierderea influenței imunoreglatorii a infestației helmintice (stimularea celulelor T reglatorii) în cazul copiilor

susceptibili ceea ce ar putea determina creşterea severității atopiei şi astmului. Sensibilizarea la *A. lumbricoides* poate fi rezultatul expunerii actuale sau un răspuns anamnestic la acest parazit sau alți helminți.

CONCLUZII

Prezenta cercetare demonstrează o asociere puternică între sensibilizarea la *A. lumbricoides*, severitatea crescută şi morbiditatea cauzată de astm. Această asociere este cel mai probabil mediată de un grad crescut de atopie în rândul copiilor cu astm sensibilizați la *A. lumbricoides*. Studii longitudinale extensive sunt necesare pentru a demonstra dacă această asociere este rezultatul stopării supresiei atopiei în cazul copiilor cu astm care primesc tratament antihelmintic şi/sau protecției împotriva helmintiazei în cazul copiilor cu astm şi atopie severă. Indiferent de mecanismul sensibilizării la *A. lumbricoides*, aceasta reprezintă un marcher important al severității atopiei, morbidității crescute şi severității bolii la copii cu astm.

SUPINE HYPERTENSION AND ORTHOSTATIC HYPOTENSION-A MANAGEMENT CHALLENGE (Abstract): We report the case of an 80-year-old patient, treated for hypertension (HT), with history of stroke, mesenteric artery thrombosis, ischemic coronary artery disease and lower limb peripheral artery disease, who was admitted to our department for dizziness and recurrent attacks of syncope. The patient also has a recent diagnosis of Parkinson's disease. Cardiac and reflex syncope were excluded by specific tests. Syncope due to orthostatic hypotension (OH) was confirmed by active standing test. The major issue for clinician was the therapeutic approach for supine HT associated with OH. The optimal schedule for HT was established. Midodrine, the only available medication, was added with satisfactory effects on OH. Lifestyle modification was considered an essential step for achieving the therapeutic success. **Keywords**: SUPINE HYPERTENSION, ORTHOSTATIC HYPOTENSION, SYNCOPE, ACTIVE STANDING TEST.

Of the multiple aspects of blood pressure (BP) control, the coexistence of supine hypertension (HT) and orthostatic hypotension (OH) entail therapeutic challenges, given that the treatment for one condition can aggravate the other. Supine HT associated with OH is a form of autonomous dysfunction. It involves high BP levels during clinostatism and a clinically significant drop of BP when changing position to standing, which may cause dizziness, presyncope or syncope. OH can be easily diagnosed using active standing test or a tilt-test. Selecting the most appropriate therapy for each patient remains the key issue in this situation.

CASE REPORT

We present the case of an 80-year-old patient, from rural area, former heavy smoker (60 packs/year, until 6 years ago), who was admitted for dizziness, presyncope and recurrent syncope, systolic blood pressure (SBP) levels between 90-160 mmHg and intermittent claudication with walking distance of approximately 20 meters. The patient has a long history of hypertension and is treated since 2012 with Candesartan 16 mg daily and Lercanidipine 10 mg daily. The evolution was marked by numerous cardiovascular events. In 2014 the patient suffered a stroke, caused by an internal carotid artery stenosis, documented

by Doppler ultrasound scan and treated via endarterectomy. One year later, the patient has two episodes of paroxysmal atrial fibrillation, converted to normal sinus rhythm after Amiodarone treatment, but without antiarrhythmic and anticoagulant prophylaxis. In 2016, the patient is admitted for acute coronary syndrome without ST segment elevation. Coronary angiography revealed tricoronary lesions with indication for medical therapy (Rosuvastatin 20 mg daily, Bisoprolol 5 mg daily, Ramipril 5 mg daily, Clopidogrel 75 mg daily). The same year, the patient developed digestive symptoms, consisting of intense and recurrent abdominal pain, with no apparent cause following gastrointestinal endoscopy and abdominal-pelvic ultrasound scan. An abdominal CT scan was performed and revealed an incomplete thrombosis of the superior mesenteric artery, for which anticoagulant therapy was provided using Rivaroxaban 20 mg daily. In 2017, the patient presents intermittent claudication, as a clinical manifestation of lower limbs peripheral artery disease, which justified the admission into the clinic. Digital substraction peripheral angiography documents multiple bilateral superficial femoral artery stenoses and tibial-peroneal occlusion, which limits the recommendations on revascularization. A major aspect for the therapeutic approach was the association with rigid type Parkinson's disease, which was recently diagnosed and treated with Levodopa/Carbidopa 250/25 mg per day and Rasagiline 1 mg per day. Physical examination shows asymmetric facies, hypotonia and mild right upper limb tremor, right carotid and bilateral femoral murmur, absence of bilateral popliteal pulse, supine BP 160/80 mmHg, and orthostatic blood pressure 150/70 mmHg. The biochemistry report revealed the following data: fasting plasma glucose 89 mg/dL, total cholesterol 153 mg/dL, triglycerides 86 mg/dL, uric acid 6.7 mg/dL, creatinine 0.92 mg/dL, creatinine clearance 80 mL/min/1.73m^2, AST 25 U/L, ALT 18 U/L. The main issue in this case was elucidating the etiology of the episodes of dizziness, presyncope and recurrent syncope. According to the diagnostic algorithm for syncope (1), we considered the cardiac causes, reflex-related causes, and the cause that was secondary to orthostatic hypotension (OH). Echocardiography examination ruled out cardiac syncope caused by structural disorders; ECG only documented the following: concentric left ventricular hypertrophy (interventricular septum 14 mm, posterior wall 12 mm), lack of segmental abnormal wall motion and preserved ejection fraction (EF 60%), aortic valve without any hemodynamically significant lesions (peak aortic velocity 2 m/s, peak gradient 15 mmHg), normal mitral valve. The arrhythmic cause cannot be taken into consideration given the ECG maintenance of sinus rhythm at 60/min after stopping the betablocker and Holter ECG monitoring/24 hours without cardiac arrhythmias and conduction disturbances. The matter of reflex syncope was analyzed owing to carotid sinus hypersensitivity, considering the left carotid endarterectomy followed by postoperative alteration of baroreceptor sensitivity (2). Carotid sinus massage would have been necessary for confirmation, which is not recommended due to the presence of calcified atheromatous plaques on the two common carotid arteries and on the right internal carotid artery, as evidenced by Doppler ultrasound scan. Of the causes for syncope due to OH in the presented patient,

we continue to consider the primary failure of the autonomic nervous system caused by Parkinson's disease and the drug-related cause (i.e., medication used for Parkinson's disease and hypertension). As tilt-test was not available, active standing test, also known as Schellong test, was conducted and it confirmed OH without tachycardia (fig. 1). Given that Parkinson's disease is associated with OH and supine HT, we conducted a 24-hour Ambulatory Blood Pressure Monitoring (ABPM), which revealed a reverse-dipper profile (fig. 2). Regarding the therapeutic approach, the problem referred to the fact that hypertension medication can aggravate OH. Non-pharmacological measures are important for controlling both OH and HT. The patient was recommended the following (1): ingesting 500 ml fluids quickly when standing up, snacking before going to sleep, sleeping position with the head raised, compression socks, avoiding extended periods of orthostatism, as well as avoiding excessive consumption of salt. Also, it is necessary to avoid medications that trigger/maintain/aggravate OH (2). From this point of view, although it may cause OH, Parkinson's disease medication is necessary. Hypertension medication can also lead to OH. It is for this reason that the therapeutic plan included Amlodipine 10 mg daily and Losartan 50 mg daily, with adequate control of BP, along with Midodrine 2.5 mg per day for a period of 7 days, and subsequently 5.0 mg per day, well tolerated by the patient and with a satisfactory correction of OH (supine BP 140/80 mmHg, orthostatic BP 120/80 mmHg). We continued the treatment with Rosuvastatin 10 mg/day, Clopidogrel 75 mg/day and Rivaroxaban 20 mg/day as mandated by comorbidities, Omeprazole 40 mg/day.

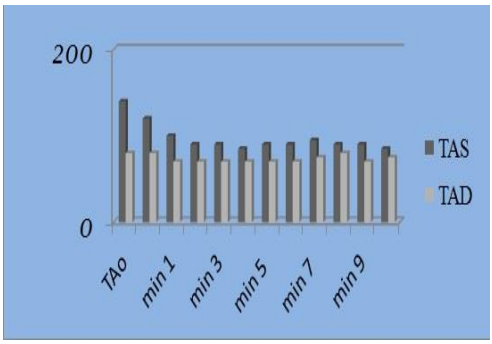

Fig. 1. Active standing test revealed a drop in SBP from 148 mmHg to 80 mmHg within 2 minutes, without stabilizing within up to 10 minutes.

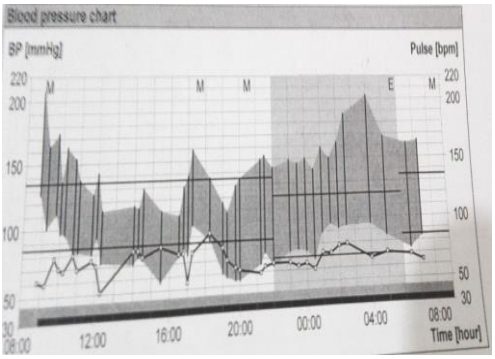

Fig. 2. Reverse-dipper BP pattern in 24-hour ABPM

DISCUSSION

The presented case highlights the importance of accurately determining the etiology for syncope and the treatment difficulties in elderly patients with comorbidities. OH is a common disorder, with a 7-30% incidence in elderly patients aged 75 years and over with normal BP levels and systemic disorders (2). OH can be caused by acute and chronic illnesses. In our patient, it was mandatory to determine chronic causes as per the ESC guidelines for the management of syncope (1). The relation with the primary autonomic dysfunction manifested in Parkinson's disease

and the age-related physiological changes is evident by means of declining baroreflex sensitivity and parasympathetic function (2, 3, 4). An additional argument is the non-tachycardic response to Schellong test, which is indicative of neurogenic OH (4). In physiological conditions, when changing position from sitting to standing there is a mild drop in BP, with activation of arterial baroreceptors and reflex increase in heart rate and myocardial contractility (5) (tab. I).

TABLE I

Physiological and pathological changes in the active standing test

Physiological changes	Pathological changes
Dropping systolic BP at least 6.5 mmHg	Dropping systolic BP > 20 mmHg
Increasing diastolic BP at least 5.6 mmHg	Dropping diastolic BP > 10 mmHg
Increasing heart rate at least 12 bpm	Increasing heart rate by >30 bpm or HR>108 bpm

In the case of autonomic failure an association of OH with supine HT would seem paradoxical, but it has a physio pathological explanation. Autonomic failure is a noradrenergic neurotransmission disorder whereby norepinephrine is not adequately released. Consequently, this impairs vasoconstriction, without a reflex increase in heart rate and reduction of intravascular volume with secondary OH (2, 6). The potential mechanisms of supine HT are the impairment of the baroreflex function, inadequate natriuresis, increased blood flow and residual sympathetic tone acting upon hypersensitive postsynaptic adrenoreceptors (5, 7, 8, 9, 10). According to other studies, in many patients both supine HT and OH were detected relatively late due to measuring BP while seating and usually resulting in normal BP levels (5, 11). According to literature data, only 2% of elderly patients with OH and HT are symptomatic (dizziness, presyncope, syncope) (10). An important practical aspect is the statement that antihypertensive medication determines OH. Antihypertensive medication is just an aggravating factor and lowering the doses alleviates symptoms (5). Clinical studies prove that the tendency for supine HT and OH in the elderly is usually plurifactorial (12, 13). Antihypertensive medication is not enough to determine the occurrence of OH, and most often there is an overlapping primary or secondary autonomic dysfunction (5, 11). Active standing test and tilt-test can confirm OH, while certain non-invasive tests such as heart rate measurement 30 minutes after the last meal, heart rate modification during the Valsalva maneuver, assessing respiratory arrhythmia during controlled breathing characterize the autonomic function (1, 2, 6). In the presented patient, the primary autonomic dysfunction within Parkinson's disease, the associated antihypertensive medication and presence of OH in Schellong test allowed for asserting the syncope etiology. What is the optimal treatment in this case? According to the 2017 Neurology Guidelines (3), the first step is to stop the medication causing OH, to the extent such a step is possible. In our patient, the medication for Parkinson's disease – which aggravated OH – could not be modified. A very important factor is the patient's education regarding the factors that can influence BP variations: avoiding rapid posture changes, extended periods of orthostatism, extensive straining during defecation or micturition, avoiding heavy meals, particu-

larly those rich in refined carbohydrates and alcohol. We would like to note the utility of swimming, as well as the minimum input of 500 ml of bolus fluids in preventing OH. Ingesting a snack before going to sleep can help reduce supine HT by inducing postprandial OH (2, 3, 4, 10, 14). As far as the antihypertensive medication is concerned, Losartan and Nifedipine R have the lowest impact on OH (4). In this case, we chose for Amlodipine instead of betablocker, considering the need to control angina and the tendency of heart rate to decrease in elderly patients as well as in patients treated for Parkinson's disease. Another useful measure could be to reduce doses in case of association with other types of drugs that have similar effects on the BP, as well as to split them in two doses – early in the morning and after lunch. This breakdown allows for 2-3 hours of activity after each dose. Also, patients must be instructed to avoid clinostatism after taking their medication. As far as OH specific medication is concerned, fludrocortisone (synthetic analogue mineralocorticoid) is contraindicated in association with supine HT (1, 11, 12). Midodrine (alpha adrenergic agonist) appears to be of an interest, as per the class II recommendations in the ESC Guidelines for syncope management (1). The important factors are up-titration to the target dose of 10 mg daily and control of the renal function (4, 11). There can also be rare occurrences of supine HT in this case (2). Pyridostigmine, a cholinesterase inhibitor, has a less marked effect on OH, but does not determine supine HT. (2) Ultimately, it can be used the parenteral administration of Octreotide, owing to its ability to generate splanchnic vasoconstriction. Droxidopa, having a similar structure to norepinephrine, is pending research for OH (2). In the presented case, Midodrine was the only available medication with satisfactory effects on OH.

CONCLUSIONS

Our case report shows the difficulty of treating HT accompanied by symptomatic OH in an elderly patient with multiple comorbidities, which requires a rigorous evaluation of the underlying etiology. In the clinical practice, patients are unique, and treatment must be customized, which reinforces the belief that "there are no illnesses, but only ill people". When pharmacological therapy is limited, it is mandatory to carefully educate the patient to improve their quality of life and ensure the therapeutic success.

NEWS

NANOFIBERS FOR WOUND HEALING

Nanofibers resemble the natural extracellular matrix of the human body. Furthermore, polymer nanofibers provide an ideal environment for wound healing. A recent study conducted at Lund University in Sweden aimed to evaluate the pure topographical effects that an underlying scaffold material may have on fibroblast behavior in a novel *in vitro* wound model, which included poly-ε-caprolactone scaffolds with different nanofiber alignment. A stencil based wound assay with L929 murine fibroblasts was used to study the closure of circular wounds over time. Triggering fibroblast migration into the wound accelerates the remodeling of the dermis. Cell viability, morphology and mobility – in fact a combination of proliferation and migration, since both occur during the natural wound healing process - were assessed. The study emphasizes the important effect of orientation on increasing cell mobility, polarization and elongating cell morphologies compared to random fiber scaffolds. (Ottosson M, Jakobsson A, Johansson F. Accelerated Wound Closure - Differently Organized Nanofibers Affect Cell Migration and Hence the Closure of Artificial Wounds in a Cell Based *In Vitro* Model. *PLoS ONE* 2017; 12(1): e0169419)

INFLUENŢA ŞI PREVALENŢA STEATOZEI HEPATICE NON-ALCOOLICE ÎN HEPATITA CRONICĂ VHB

Iuliana Pîrvulescu[1], S. Suciu[1], M. Andrei[2], Alexandru Lupu[1], M. Diculescu[1]
1. Institutul Clinic de Boli Digestive şi Transplant Hepatic Fundeni (ICBDTH)
2. Clinica de Gastroenterologie şi Hepatologie Elias

THE INFLUENCE AND PREVALENCE OF NONALCOHOLIC STEATOHEPATITIS IN CHRONIC HEPATITIS B (Abstract): The prevalence and the impact of nonalcoholic fatty liver disease (NAFLD) on chronic hepatitis B (CHB) are not well known. NAFLD as the hepatic manifestation of the metabolic syndrome (MS) is associated with obesity, diabetes mellitus and dislipidemia. **Aim**: To evaluate the prevalence and the impact of NAFLD on CHB. **Methods**: 120 patients diagnosed serologically and histological with CHB in 2006 in our center were retrospectively analyzed. Patients with self declared excessive alcohol consumption (above 20g/day for males and 10g/day for females) have been excluded. NAFLD was evaluated according to Brunt's score, while histology activity index (HAI) and fibrosis stage for CHB were estimated using Knodell score. The patients were divided in 2 groups: patients with CHB without steatosis (n=61) and with steatosis (n=59). **Results:** Out of 120 patients with CHB (male/female=76/44, median age=40.41), 49.15% had steatosis. No statistically significant differences among fibrosis stages, HAI and the aminotransferase levels was found between the two groups (p=0.320, p=0.228, and p=0.128). The presence of NAFLD associated with CHB was significantly correlated with age (p=0.001) and MS (p=0.051). In patients with CHB and steatosis, significant correlations between female sex and the presence of MS (p=0.007) as between HAI and age (p=0.003) were found. **Conclusions:** NAFLD was detected at 49.16% of patients with CHB. A positive correlation with age and MS (obesity, diabetes mellitus and/or dislipidemia) was observed. No significant correlations between NAFLD and the aminotransferase levels or histological features have been found. **Key words**: NONALCOHOLIC STEATOHEPATITIS, CHRONIC HEPATITIS B, METABOLIC SYNDROME

Infecţia cu virusul hepatitic B reprezintă o problemă de sănătate publică în lume, fiind responsabilă pentru una dintre cele mai frecvente boli la nivel mondial. Se estimează că peste două miliarde de persoane sunt infectate cu virusul hepatitic B (VHB), iar 350 milioane au infecţie cronică cu VHB (1).

Conform rezultatelor unui studiu epidemiologic recent, prevalenţa hepatitei cronice B în România este de 4,32 % (2), ceea ce înseamnă că, la o populaţie de 21 milioane locuitori, aproape 1 milion de persoane sunt infectate cu VHB.

În ultimul deceniu, boala ficatului gras nonalcoolic (NAFLD) reprezintă o altă problemă reală socială şi medicală în lume, reprezentând un spectru de condiţii clinico-patologice cu potenţial evolutiv sever ce cuprinde steatoza hepatică, steatohepatita (NASH) şi ciroza hepatică, în absenţa consumului de alcool în cantităţi hepatotoxice şi a altor etiologii de boală hepatică.

Prevalenţa NAFLD şi NASH în populaţie nu se cunoaşte cu exactitate, studiile efectuate până în prezent relevând, în funcţie de gradul de industrializare, tipul de dietă şi populaţia inclusă, valori diferite de 17-33%, respectiv 5-17% (3).

TABELUL I
Criteriile ATP de diagnostic a sindromului metabolic

3 sau mai multe din următoarele:
• Obezitate centrală abdominală (Talie>102 cm la bărbaţi, >88 cm la femei)
• Trigliceride serice >150mg/dl
• HDL-Colesterol <40mg/dl
• Tensiunea arterială >130/85mmHg
• Glicemia a jeun >110mg/dl

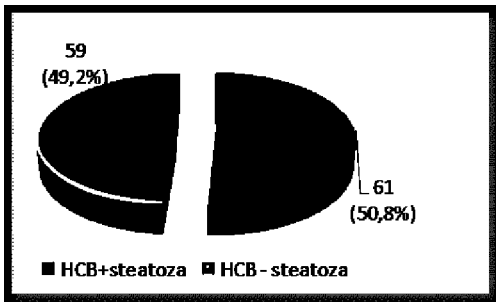

Fig. 1. Distribuţia pacienţilor în loturi de studiu şi prevalenţa steatozei hepatice.

Într-un studiu recent publicat de Poynard în Franţa, prevalenţa steatozei şi steatohepatitei (evaluate prin teste noninvazive - SteatoTest şi NashTest) în populaţia generală a fost de 18,1%, respectiv 1,3%. (4)

Prevalenţa NAFLD se estimează că va creşte în paralel cu creşterea incidenţei factorilor de risc pentru apariţia steatozei hepatice (obezitatea, insulinorezistenţa, diabetul zaharat şi alte componente ale sindromului metabolic). (5,6,7)

Având în vedere prevalenţa înaltă atât a infecţiei cronice VHB cât şi a NAFLD în populaţia generală, se estimează o incidenţă crescută a steatozei hepatice suprapuse hepatitei cronice VHB. Este bine cunoscută prevalenţa înaltă şi semnificaţia steatozei hepatice în hepatita cronică VHC. La pacienţii cu genotip 3 steatoza hepatică este direct atribuită virusului C, pe când în genotipul 1 şi 4 steatoza hepatică s-a demonstrat a fi secundară insulinorezistenţei şi componentelor sindromului metabolic. Este demonstrat faptul că atât insulinorezistenţa cât şi steatoza hepatică suprapusă hepatitei cu virus C accelerează progresia bolii, crescând gradul fibrozei hepatice. (8-11)

Comparativ cu infecţia cronică VHC, prevalenţa şi semnificaţia clinică şi prognostică a steatozei în hepatita cronică VHB este insuficient studiată.

Acest studiu analizează prevalenţa, impactul şi factorii de risc pentru steatoza hepatică suprapusă infecţiei cronice VHB la pacienţii diagnosticaţi histologic cu hepatită cronică VHB în Clinica de Gastroenterologie Fundeni, în anul 2006.

MATERIAL ŞI METODĂ

Date clinice

Au fost incluşi în studiu 120 de pacienţi diagnosticaţi serologic şi histologic cu hepatită cronică virală B (HCB) în anul 2006, în Clinica de Gastroenterologie Fundeni.

Toţi pacienţii cu AgHBs pozitiv de cel puţin 6 luni, ADN-VHB detectabil în ser şi biopsie hepatică efectuată sub ghidaj ecografic, au fost incluşi retrospectiv în studiu.

Pacienţii cu neoplazii concomitente, cu tratamente imunosupresive în ultimul an, cu anticorpi pozitivi pentru infecţia cu virusul hepatitic C sau D au fost excluşi. Alte criterii de excludere au fost : consumul excesiv declarat de alcool (> 20 g/zi pentru bărbaţi şi > 10 g/zi pentru femei), administrarea altor medicamente care pot cauza steatoză hepatică (amiodarona, corticosteroizi, tamoxifen, methotrexat), prezenţa altor etiologii de boală hepatică cronică (hepatită autoimună, ciroză biliară primitivă, boala Wilson, hemocromatoză).

TABELUL II
Distribuţia pacienţilor în funcţie de valorile transaminazelor

Steatoză da/nu			Frecvenţa	Procent	Valid Percent	Procent cumulativ
fără steatoză	Valid	Transaminaze normale	11	18.0	18.0	18.0
		Transaminaze crescute	50	82.0	82.0	100.0
		Total	61	100.0	100.0	
cu steatoză	Valid	Transaminaze normale	14	23.7	23.7	23.7
		Transaminaze crescute	45	76.3	76.3	100.0
		Total	59	100.0	100.0	

Date de laborator şi histologice

Toţi pacienţii au fost evaluaţi *clinic, antropometric* (vârstă, sex, greutate, înălţime, indice de masă corporală - BMI), *serologic* (transaminaze ALT, AST, glicemie, colesterol, trigliceride, AgHBs, încărcătură virală : ADN-VHB cantitativ) şi *histologic* (coloraţie hematoxilin-eozină, Masson trichrome, scor Knodell, steatoză hepatică : absentă $<5\%$ din hepatocite afectate şi prezentă $>5\%$ din hepatocite afectate).

Prezenţa sau absenţa sindromului metabolic a fost stabilită pe baza criteriilor ATP III (Adult Treatment Panel III) – tabelul I. Obezitatea a fost definită printr-un BMI$>$ 25 kg/m^2.

Analiza statistică

Toate datele au fost analizate utilizând programul SPSS (versiune 15.0, SPSS Inc., Chicago, IL, USA). Analiza statistică s-a făcut utilizând testul t-test pentru compararea variabilelor continue între grupuri sau în cadrul grupului, metoda chi-pătrat pentru compararea datelor calitative. P-value $<0,05$ a fost considerată statistic semnificativă.

REZULTATE

Cei 120 de pacienţi incluşi în studiu au avut vârste între 17 şi 62 ani, cu o vârstă medie de 40.41 $\pm$ 12,12 ani şi cu un raport femei/bărbaţi de 44/76 (36.7% femei, 63.3% bărbaţi).

Pacienţii diagnosticaţi cu hepatită cronică VHB au fost împărţiţi în două grupuri de studiu : pacienţi fără steatoză hepatică (61 de pacienţi) şi cu steatoză hepatică (59 de pacienţi). Prevalenţa steatozei hepatice în lotul studiat a fost de 49.16%. (Fig. 1)

Distribuţia pacienţilor cu valori normale/ crescute ale transaminazelor în cele două grupuri de studiu este descrisă în tabelul II.

Nu s-au înregistrat diferenţe semnificative statistic în ceea ce priveşte valorile transaminazelor (ALT cu valori crescute $>$N, ALT cu valori normale) la pacienţii cu steatoză hepatică suprapusă hepatitei VHB comparativ cu cei fără steatoză hepatică (p-value $=0,128$) (Fig.2).

Prezenţa steatozei hepatice la pacienţii cu infecţie cronică VHB se corelează semnificativ statistic (p-value$=0.003$) cu vârsta înaintată (mai mare decât vârsta medie >41 ani) (Fig. 3).

Din grupul de pacienţi cu steatoză hepatică, 64.4% prezintă cel puţin o componentă a sindromului metabolic (MS), comparativ cu doar 18% din pacienţii lotului fără steatoză hepatică asociată.

Prezenţa a cel puţin unei componente a

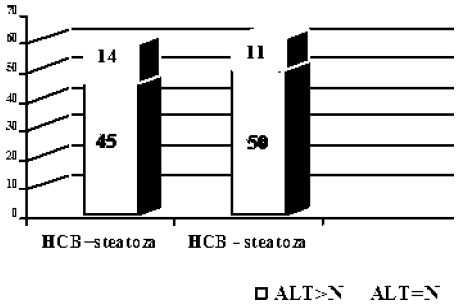

Fig. 2. Repartiţia pacienţilor în funcţie de nivelul transaminazelor.

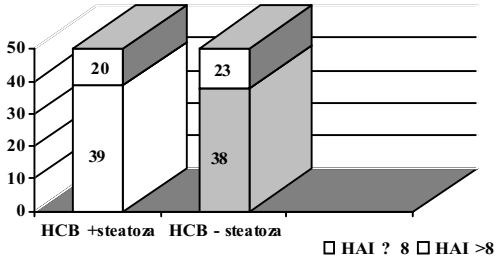

Fig. 4. Repartiţia în funcţie de activitatea necroinflamatoare.

sindromului metabolic se asociază semnificativ statistic (p-value=0.051) cu prezenţa steatozei hepatice.

În ceea ce priveşte necroinflamaţia hepatică evaluată prin scorul Knodell (considerând inflamaţie uşoară HAI ≤ 8 şi semnificativă HAI >8), nu există diferenţe statistic semnificative (p-value=0,320) între cele două grupuri analizate (Fig.4).

Dintre pacienţii care asociază steatoză hepatică 50.8% prezintă fibroză semnificativă (stadiul fibrozei ≥ 2), comparativ cu 6.1% din pacienţii fără steatoză hepatică.

Prezenţa steatozei hepatice la pacienţii cu hepatită cronică VHB se corelează semnificativ statistic (p-value=0.001) cu stadiul fibrozei hepatice (Fig.5).

În grupul de pacienţi cu steatoză hepatică supraimpusă hepatitei cronice VHB, s-au decelat corelaţii semnificative statistic între genul feminin şi prezenţa a cel puţin unei componente a sindromului metabolic (p-value =0.007).

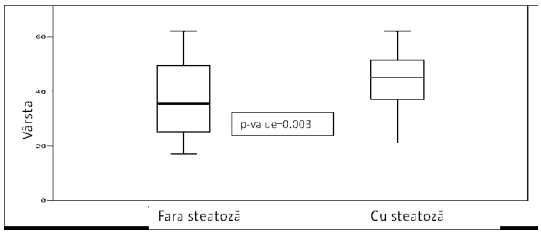

Fig. 3. Asocierea steatozei hepatice la pacienţii cu HCB.

În grupul de pacienţi cu steatoză hepatică au fost evidenţiate corelaţii semnificativ statistic (p-value=0.003) între scorul necroinflamator (HAI) şi vârsta avansată (Fig.6).

DISCUŢII

Acest studiu analizează prezenţa, impactul şi factorii de risc pentru steatoza hepatică asociată hepatitei VHB la un grup de pacienţi evaluaţi în anul 2006 în Clinica de Gastroenterologie Fundeni, Bucureşti.

În studiul nostru, prevalenţa steatozei hepatice a fost de 41.16% la pacienţii cu hepatită cronică VHB dovedită prin puncţie biopsie hepatică.

Prevalenţa a fost similară cu cea din alte studii (32-77%) (12-15), dar mult mai înaltă comparativ cu studiile din Grecia şi America de Nord, cum ar fi cel al lui Thomopoulos et al. (18%), Sanyal et al. (4,5%) şi Czaja et al. (24%). (16-18)

Este posibil ca variaţia mare a prevalenţei dintre studiile menţionate să se datoreze numărului relativ mic de pacienţi incluşi, diferenţelor etnice, dar şi a modului/corectitudinii de apreciere a consumului declarat de alcool.

În studiul nostru nu s-a evidenţiat o corelaţie pozitivă între prezenţa steatozei hepatice suprapuse infecţiei VHB şi valorilor crescute ale transaminazelor serice.

Acest studiu a plecat de la ipoteza că steatoza hepatică agravează atât necroinflamaţia ca şi fibroza hepatică în hepatita cronică VHB, similar cu hepatita cronică VHC.

Nu s-au găsit corelaţii semnificative statistic între prezenţa steatozei hepatice şi sco-

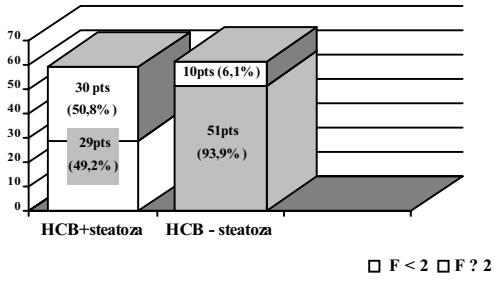

Fig. 5. Asocierea fibrozei hepatice.

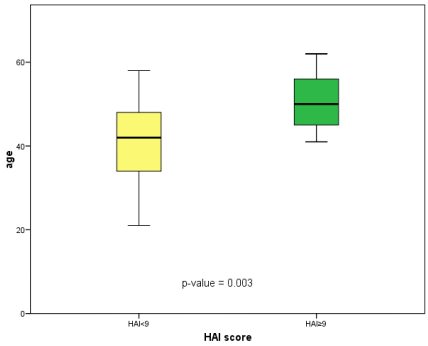

Fig. 6. Corelaţia scorului necroinflamator cu vârsta înaintată.

rul necroinflamator, nesusţinându-se astfel premisa agravării inflamaţiei hepatice de către steatoza hepatică.

Diferenţe semnificative statistic au fost demonstrate în ceea ce priveşte stadiul fibrozei hepatice între cele două grupuri de pacienţi analizate. Steatoza hepatică suprapusă infecţiei cronice VHB s-a asociat cu prezenţa fibrozei semnificative (F=2), demonstrând astfel, similar cu datele din studiile efectuate la pacienţi cu hepatită cronică VHC, rolul steatozei în progresia fibrozei la pacienţii cu hepatită VHB.

Studiul nostru demonstrează că prezenţa a cel puţin unei componente a sindromului metabolic (dislipidemie, hiperglicemie, obezitate) se asociază cu prezenţa steatozei hepatice la pacienţii cu hepatită cronică VHB, sugerând astfel că NAFLD în infecţia cronică VHB este mai probabil rezultatul factorilor metabolici ai gazdei, decât efectul direct al virusului VHB.

Adiţional, în grupul de pacienţi cu steatoză hepatică s-au evidenţiat corelaţii semnificative statistic între vârsta avansată şi scorul inflamator, precum şi între sexul feminin şi prezenţa a cel puţin a unei componente a sindromului metabolic.

În concluzie, steatoza hepatică se întâlneşte relativ frecvent la pacienţii cu hepatită cronică VHB, fiind puternic asociată cu factorii metabolici. Comparativ cu hepatita cronică VHC, steatoza în hepatita cronică VHB se asociază cu vârsta şi cu fibroza hepatică avansată, dar nu se corelează cu necroinflamaţia hepatică şi valoarea transaminazelor (19-21).

HIGH MYOPIA AND GLAUCOMA - A CHALLENGE IN DIAGNOSIS. REVIEW (Abstract). The increasing global prevalence of myopia has significant consequences, as it predisposes to severe ocular pathologies. Differentiating early-stage glaucoma from myopia is challenging due to common clinical features. Diagnosing glaucoma in a highly myopic patient who has an abnormal optic nerve and an abnormal visual field, but normal intraocular pressure is a problem. Although the mechanisms responsible for glaucoma in myopic patients are poorly understood, it has been suggested that the optic nerve head in myopic eyes is more susceptible to glaucomatous damage. Mechanical stress induced by increased axial length of the globe and oxidative stress play a key role in the development of glaucoma in myopic eyes. Optic coherence tomography assessment of macular ganglion cells layers rather than retinal nerve fiber layer is valuable. Visual field testing should be used routinely in myopic patients, in order to facilitate the detection of early glaucoma. This review summarizes the difficulties in diagnosis of glaucoma in high myopic patients. **Keywords:** HIGH MYOPIA, GLAUCOMA, OPTIC COHERENCE TOMOGRAPHY, VISUAL FIELD.

Glaucoma is the leading cause of irreversible blindness in the adult population worldwide (1). It is a progressive optic neuropathy characterized by progressive structural loss of retinal ganglion cells and optic nerve damage that results in characteristic visual field loss. Early identification of the disease is very important, because appropriate treatment can prevent the progression of the disease.

Because primary open-angle glaucoma (POAG) is usually asymptomatic until the advanced stage, it is important to establish an effective screening tool for early detection of the disease. Many studies have investigated the risk factors associated with glaucoma (2). Elevated intraocular pressure (IOP) is an important risk factor for POAG (3). Evidence shows that lowering IOP reduces the risk of development of glaucoma (2). In addition, there is growing evidence that other risk factors like age, gender, race, refractive errors, heredity and systemic factors may play a role in glaucoma pathogenesis (4). Epidemiologic studies support the idea that high myopia is a risk factor for the progression of glaucomatous optic neuropathy (5).

The increasing global prevalence of myopia has significant consequences as it predisposes individuals to severe ocular pathologies. Differentiating early-stage glaucoma from myopia is challenging due to common clinical features. Diagnosing glaucoma in a patient who is highly myopic and has abnormal optic discs and an abnormal visual field, but normal pressures is a challenge. There are three main ways to assess glaucoma: changes in the optic nerve, which can be measured by fundus photos and optic coherence tomography imaging (OCT), changes in the visual fields (VF) indicating a progressive loss of retinal nerve fiber layer (RNFL) and elevated intraocular pressure (IOP) (6). Although the mechanisms responsible for glaucoma in myopic patients are poorly understood, it has been suggested that the optic nerve head in myopic eyes is more susceptible to glaucomatous damage because of the changes in connective tissue structure (2).

Myopia is the most frequent refractive error, which typically accelerates during the teenage years (7). Near-work activities were thought to contribute to the development of myopia by leading to constant ciliary muscle contraction and more accommodation, to which the eye responds by axial elongating. More time spent indoors has also been implicated, since exposure to light stimulates dopamine release, which is thought to reduce the axial length (8). Teenage and adult-onset myopia is characterized by an axial length of < 26 mm and refractive errors of up to -5 diopters (D). In high myopia, the extreme refractive errors of more than -6.00 D and an axial length of > 26 mm are associated with progressive degenerative changes of the fundus, optic disc deformation, retinal thinning, and choroidal atrophy (9).

The link between myopia and glaucoma

High myopia is associated with an increased risk of ocular complications such as premature cataracts, glaucoma, retinal detachment, and macular degeneration (10, 11). The prevalence of myopia varies across populations of different regions and ethnicities. High myopia is more common in Asia (12, 13). Scientists have not yet establish an effective treatment to prevent the progression of high myopia. Population-based studies indicate that the risk of glaucoma increases with the increasing degree of myopia. Most studies have shown that high myopia is associated with an increased risk of POAG. The Blue Mountains Eye Study found a strong relationship between POAG and myopia (14). In the Barbados Eye Study, a myopic refraction was one of risk factors for POAG in adult black people (15). The Beaver Dam Eye Study suggested that, after considering the effects of age and sex, persons with myopia were 60% more likely to have glaucoma than those with emmetropia (16). Patients with moderate or high myopia had a 3 times higher risk of POAG compared with those with emmetropia (17).

Pathogenesis of myopic glaucoma

Given a strong epidemiologic relationship between myopia and glaucoma, there is great interest in understanding the mechanisms between the two diseases. Abnormalities of the lamina cribrosa associated with high myopia may explain the higher susceptibility of myopic eyes to glaucoma at any IOP level (18). The mechanisms by which myopia predisposes to glaucoma development are still unknown. Though, two principal theories try to explain the progressive damage of retinal ganglion cell layer (GCL). The mechanical theory sug-

gests that the damage is to the lamina cribrosa, where axons exit the eye. This can be induced by increased IOP and a fragile sclera or by exacerbated shearing forces due to elongation of the eye. In high myopia there is a loss of collagen and proteoglycans at the scleral level. This changes lead to loss of sphericity, the scleral canal is widened, the lamina cribrosa is thinner and the choroid atrophy occurs.

The vascular theory supports that insufficient ocular perfusion secondary to increased IOP is a risk factor for glaucomatous optic neuropathy (18). One important factor implicated in the vascular theory is the oxidative stress, as a result of myopia-associated retinal pigment epithelium and choroid atrophy. The increased level of reactive oxygen species and the reduced antioxidant protection mechanisms play a pathogenic role in POAG (19). Retinal tissue is highly susceptible to oxidative stress because of the high oxygen demands coupled with its high polyunsaturated fatty acid content (20).

Differentiating early-stage glaucoma from high myopia

Glaucoma is characterized by increased IOP, altered VF and damage to the optic nerve head on fundus examination and OCT measurements. Assessment of IOP alone can prove insufficient for identifying glaucoma in high myopic patients due to the fact that IOP dependents on corneal thickness. Corneal thickness is characteristically thinner in myopic eyes (21). Differences in biomechanical properties of the cornea may modify IOP measurements. Moreover, we need to keep in mind that there is also normal tension glaucoma. It is important to remember that the IOP is often more elevated in patients with high myopia, being greater during sleep. A cross-sectional study demonstrated that myopia was correlated with increasing IOP at baseline (16). Studies showed that, for a given IOP in eyes with POAG, optic nerve damage appears to be more important in highly myopic eyes with large optic discs than in non-highly myopic eyes (22). It is necessary to check the diurnal pressure, several times a day. The appearance of normal IOP is one of the factors that makes these patients challenging to diagnose. It is best to obtain multiple readings at different times of day, since one eye pressure reading is only a single measurement out of a continuum IOP fluctuation.

The structural changes of glaucomatous optic neuropathy include generalized enlargement of the optic disc cup, localized notching or narrowing of the optic disc rim, and violation of the Inferior-Superior-Nasal-Temporal rule (the thickness of disc rims beginning with the inferior rim, followed by the superior rim, the nasal rim, and the temporal rim) (23). Early detection of glaucomatous optic disc changes is difficult in patients with high myopia because myopic discs have large diameters, a larger cup disc ratio, shallow and concentric disc cupping, and a high frequency of disc tilting (24, 25). The optic disc of many high myopia patients are accompanied by tilt, torsional or pale appearance, or peripapillary atrophy, which makes the evaluation of the retinal rim difficult (26). The fundus examination is made on dilated pupil (fig. 1, 2).

There is no consensus about the best method to detect progression of VF loss. Yi-An *et al*. (27) found that IOP and high myopia were risk factors for progression of VF loss in POAG patients. Ding *et al*. (28) studied 1,434 visual fields of high myopic

patients. They found that 16.1% of defects in the myopic subjects were the same as those found in glaucoma patients, while 3 % of the eyes had defects that looked like dense arcuate scotomas. The study group did include a few glaucoma suspects, but most were healthy high myopes. The VF in high myopia reveals the enlargement of the blind spot, the reduction of retinal sensitivity, arcuate temporal scotoma and cecocentral scotoma. It is important to remember that the scotomas do not respect the horizontal meridian (fig. 3). In glaucoma, VF examination has an important role in evaluating the disease progression. The defects respect the horizontal meridian. The most frequent defects found in glaucoma patients are: paracentral scotoma, Bjerrum arcuate scotoma, nasal step, ring scotoma (29) (fig. 4).

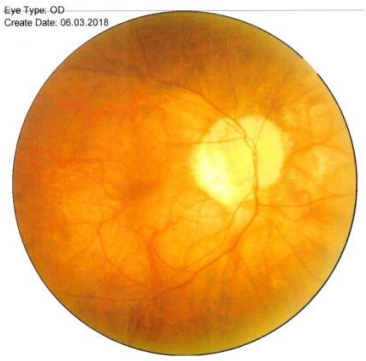

Fig. 1. Fundus examination in a high myope

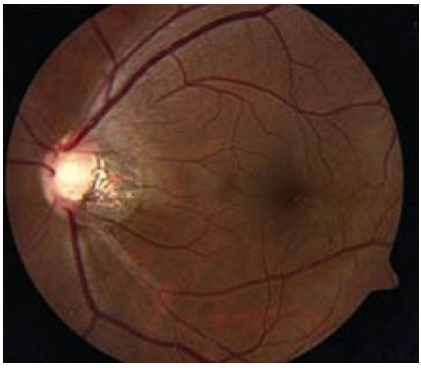

Fig. 2. Fundus examination in a patient with high myopia and glaucoma

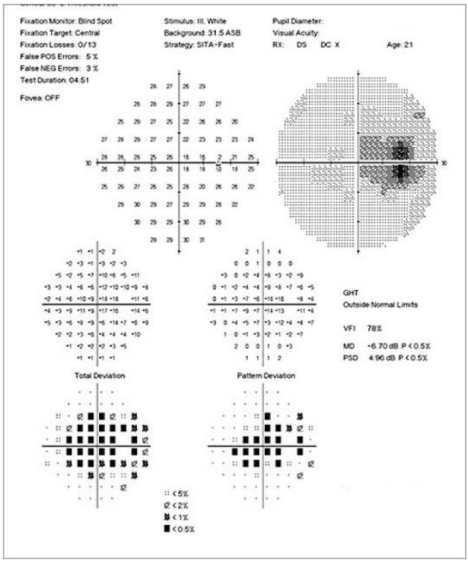

Fig. 3. Visual field - enlargement of blind spot in high myopia

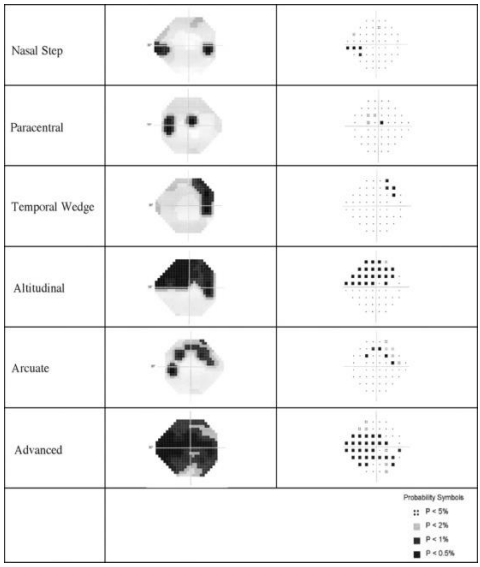

Fig. 4. Visual field defects in glaucoma (30)

Recently, computerized imaging devices such as OCT and confocal scanning laser ophthalmoscopy, have been used for the diagnosis of glaucoma. OCT is a valuable aid for detection of early glaucomatous changes. OCT images provide visualization of a thinning circumpapillary retinal nerve fiber layer (cp-RNFL), which is a classic indicator of glaucoma. However, a thin cp-RNFL is also a clinical feature of the enlarged eyes in high myopia. It is also important to remember that myopic tilt can severely affect RNFL thickness and optic nerve head parameters on OCT. Since retinal thinning typically occurs in the peripheral but not central areas, macular measurements of GCL, which are not influenced by myopic thinning of the cp-RNFL, are very important. The assessment of GCL parameters is a useful technique in association with cp-RNFL thickness, for evaluating patients with glaucoma and high myopia (31).

The OCT in high myopia shows more RNFL abnormalities in the nasal, superior and inferior quadrants, while in glaucoma in the temporal and inferior quadrants (fig.5, 6). OCT RNFL thickness map in myopic eyes requires careful consideration of the distribution pattern of the RNFL bundles. RNFL measurement is sensitive for detection of glaucoma, and the extent of RNFL damage correlates with the functional deficit in the visual field. Shoji (32) studied 93 glaucoma and 86 non-glaucoma patients with high myopia and compared the macular GCL and cp-RNFL measurements. They found that macular GCL parameters were able to detect glaucoma, and they also showed that cp-RNFL measurements were significantly related to both high myopia and glaucoma.

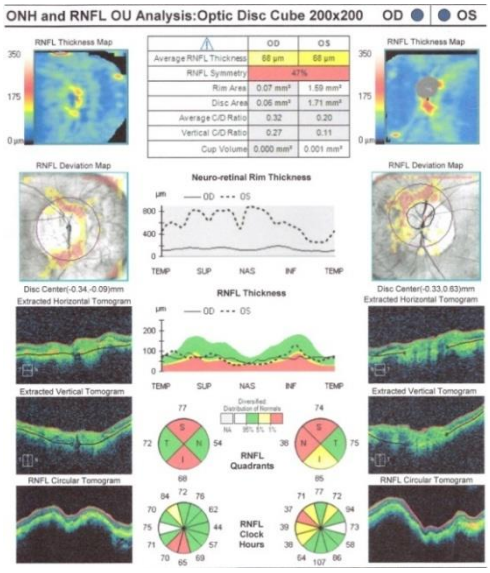

Fig. 5. OCT - RNFL in high myopia

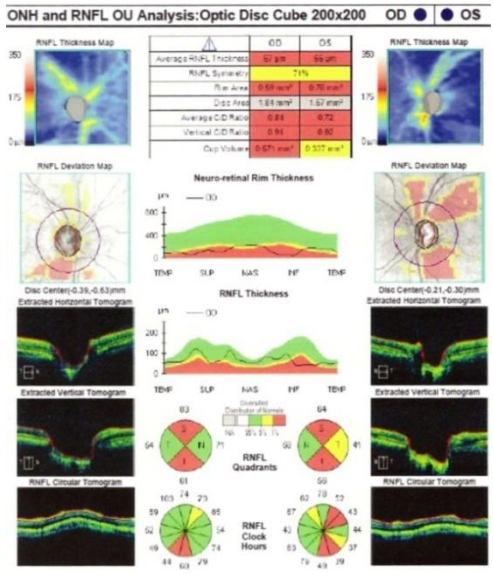

Fig. 6. OCT - RNFL in glaucoma

It remains unclear if the optic nerve damage is due to torsional changes at the level of the lamina cribrosa during axial elongation. Multiple studies have reported

cross-sectional changes in the lamina cribrosa and peripapillary atrophy using OCT imaging techniques (33-36).

New approaches

Early detection of any pathology provides potential for preventing the disease. Scientists investigate new interventions to control excessive ocular growth and limit myopic progression. One approach involves ocular strategies such as bifocals, and a new contact lens design. Another approach is based on behavioral strategies such as modified ergonomics in the classroom. The use of atropine has been shown to reduce the rate of axial growth (37). One of the most important approaches for monitoring early glaucoma changes in high myopes is to perform routine visual field testing. While analyzing the OCT, it's important to make sure that any significant defects seen on OCT correspond to visual field defects.

If it's not obvious whether the patient has glaucoma or just high myopia, one can choose to monitor the patient, looking for the earliest confirmed deterioration in test results over time. This may be an acceptable choice, depending on the age of the patient, the patient's lifestyle and the amount of reserve vision that remains unaffected (6). If one chooses to monitor the patient, it is important to make serial testing using the same machine. At first, this must be done more frequently, and then slowly spaced out if no change is detected. Furthermore, it is advisable to monitor the IOP and the optic nerve in comparison to baseline stereo disc photos.

CONCLUSIONS

From our review and summing up the studies above mentioned, we can conclude that high myopia often makes detecting glaucoma difficult, because optic nerve features may confound glaucomatous changes. Although the mechanisms responsible for glaucoma in myopic patients are poorly understood, it has been suggested that the optic nerve head in myopic eyes is more susceptible to glaucomatous damage. In addition, pathologic myopia may cause visual field defects and retinal nerve fiber layer thinning that are indistinguishable from those found in glaucoma patients. Macular ganglion cell layer parameters are able to detect early glaucoma, while cp-RNFL measurements are related to both high myopia and glaucoma. Myopic patients presenting with visual field and OCT defects should be observed conservatively unless they demonstrate progression. It is important to investigate if there is a decrease in the rate of visual field loss and RNFL thinning after cessation of progressive myopia.

HISTOPATHOLOGIC DIFFERENCES PARTIALLY DISTINGUISH SYNDROMIC AORTIC DISEASES

A variety of syndromic diseases such as Marfan syndrome, Loeys–Dietz syndrome, and bicuspid aortic valve with aneurysm along with risk factors of smoking and hypertension result in ascending aortic aneurysms and dissections. Historically, a complicated variety of terms have been used to describe a range of histopathology that are present in resected specimens. As a result, no consistent patterns of histopathology have been reported. We used the recent Society for Cardiovascular Pathology/Association for European Cardiovascular Pathology consensus statement on nomenclature and diagnostic criteria for noninflammatory aortic disease to blindly evaluate 148 surgically resected specimens. We found that overall patterns of histopathologic changes could separately cluster bicuspid aortic valve and no syndromic subjects from Marfan and Loeys–Dietz subjects. Marfan syndrome cases significantly had more overall medial degeneration and mucoid extracellular matrix accumulation than other syndromes. Smooth muscle cell nuclei loss was a feature of aging and not a feature of Marfan or Loeys–Dietz syndrome subjects. The authors conclude that a consistent use of histologic and histopathologic descriptors can help discriminate different etiologies of ascending aortic aneurysms (Waters KM, Rooper LM, Guajardo A and Halushka MK. Histopathologic differences partially distinguish syndromic aortic diseases. *Cardiovascular Pathology* 2017; 30: 6-11).

CHILDREN CHRONIC HEPATITIS C: ARE EXTRAHEPATIC MANIFESTATIONS AN ARGUMENT FOR STANDARD THERAPY? (Abstract): Chronic hepatitis C is still an important health problem in children. Adequate management of those pacients should be focused on two directions: dissapearance or reduction of the viral load (conventional antiviral therapy) and treatment of autoimmune manifestations (corticoids, plasmapheresis, cytotoxic agents). **Aim:** To associate extrahepatic manifestations with other disorders and to evaluate the evolution under specific (antiviral) and non-specific therapy. **Materials and methods:** 43 children diagnosed with chronic hepatitis C and followed in the 2nd Pediatric Clinic Iaşi between January 2005 and June 2010. **Results and discussions:** most children were diagnosed accidentally or for etiological investigations for elevated liver enzymes. Extrahepatic manifestations were found in 41.86% of pacients, most of them with articular, skin and hematologic disorders, but also depression (2 cases) in those receiving interferon. **Conclusions:** In children, extrahepatic manifestations in chronic hepatitis C infection are more rare than in adults, especially with articular involvement. In certain cases, interferon therapy can trigger those manifestations with an immune mechanism. It is essential to evaluate the autoimmunity markers before proceeding with antiviral therapy. **Key words:** CHRONIC HEPATITIS C, CHILDREN, EXTRAHEPATIC, INTERFERON

De la descoperirea VHC în 1989, cunoştinţele de epidemiologie, istorie naturală şi eficientizarea răspunsului VHC la terapia antivirală s-au acumulat, scriind o istorie de succes la adulţi. Progresul a fost mult mai lent pentru copiii infectaţi, existând lacune majore în privinţa datelor care sprijină deciziile clinice, prevalenţa mai mică în cadrul acestui grup special de pacienţi şi având în vedere consideraţiile de ordin social, material şi etic în derularea studiilor clinice la copii (1). În România, prevalenţa VHC este de 4,9%, plasând ţara noastră pe locul 1 în Europa ca număr de hepatite C înregistrate şi pe locul 4 ca rată a mortalităţii cauzate de bolile hepatice (Institutul de Sănătate Publica Cluj-Napoca). Copiii infectaţi cronic cu VHC sunt deseori subdiagnosticaţi şi, ca atare, netrataţi multă vreme, vor ajunge la o afectare hepatică severă pe termen lung. De asemenea, majoritatea sunt asimptomatici, uneori prezentând doar astenie sau durere abdominală (semne necaracteristice), fiind astfel dificil de identificat. La acestea se adaugă transmiterea verticală, cauza primară în epidemiologie (în 60% din cazuri), deşi riscul mediu al transmiterii de la mamă la copil este doar de 5 %, mult mai mic decât în cazul hepatitei B, şi faptul că vârsta adolescenţei îi aduce la un grad de risc crescut pe cei consumatori de droguri, pe amatorii de tatuaje şi piercing, pe lângă riscul legat de transfuziile de sânge şi produse derivate.

Într-o meta-analiză care evaluează riscul transmisiei verticale a VHC, s-a arătat că şansa de transmitere este dublă la mamele coinfectate VHC/HIV, cu o rată a transmisiei verticale a VHC fără HIV care variază între 4-10%, şi la mamele coinfectate VHC/HIV cu viremie VHC detectabilă - un risc de 2,82 ori mai mare (3). Iată de ce conştientizarea problemei şi identificarea precoce a copiilor infectaţi sunt prioritare, asigurând şanse mai mari de intervenţie terapeutică eficientă.

Caracteristica principală a hepatitei cronice cu virus C este persistenţa infecţiei virale în timp, cu progresia lentă a fibrozei parenchimului hepatic şi, de asemenea, tropismul limfatic demonstrat. În general, copiii au mai puţină inflamaţie, fibroză şi steatoză decât adulţii, probabil datorită duratei mai scurte a infecţiei. Fibroza semnificativă şi chiar ciroza pot apărea însă şi în perioada copilăriei, aceşti pacienţi având risc crescut de boală hepatică terminală când vor deveni adulţi. Rămân necunoscute rata progresiei bolii, factorii de risc ai progresiei, precum şi dacă această progresie se face sau nu după un model liniar. În ceea ce priveşte clearance-ul spontan, acesta este mai frecvent la copiii care au dobândit infecţia la vârstă mică şi la cei cu transaminaze normale (2,4). Genotipurile 1a şi 1b sunt prevalente la adolescenţi şi adulţi tineri, iar la copil sunt mai frecvente infectările cu genotipurile 3 şi 4.

Totuşi, în ţara noastră, majoritatea cazurilor sunt cu genotip 1. Copiii infectaţi cu genotipul 3 au cea mai mare probabilitate de apariţie a clearance-ului spontan şi răspund în mare măsură la tratamentul cu IFN (4,5). Interacţiunea complexă între anumite caracteristici virale şi răspunsul imun al gazdei determină o mare variabilitate genetică a VHC, ca mecanism prin care VHC evită supravegherea imună. Prezenţa simultană la acelasi individ a variantelor virale diferite, dar strâns înrudite au primit denumirea de quasispecii. Acestea apar în special la genotipul 3 şi pot compromite răspunsul mult mai bun la tratament al acestui genotip. La cei cu TGP normal sau uşor crescut s-a demonstrat existenţa quasispeciilor complexe, cu creşterea numărului şi a diversităţii genetice ale clonelor virale. O heterogenitate mai mare şi o complexitate a quasispeciilor la copiii cu absenţa dovezilor biochimice a leziunii hepatice poate sugera că sistemul imun al gazdei la aceşti copii exercită o presiune imună mai mare asupra VHC, ceea ce determina implicaţii în viitor pentru terapie.

În urmă cu aproximativ 10 ani, mulţi autori au descris asocierea HVC cronică cu un grup de afecţiuni non-hepatice, heterogene, cum ar fi fibroza pulmonară, vasculitele cutanate, glomerulonefrita, ulcerul Mooren, porfiria cutanea tarda, lichenul plan (2), care au fost considerate drept manifestări extrahepatice ale infecţiei cronice HVC. Cercetătorii şi-au menţinut interesul stabilirii unor conexiuni între hepatita cronică cu virus C şi unele afecţiuni autoimune, cum sunt crioglobulinemia, sindromul Sjogren, artrita reumatoidă, poliarterita nodoasă, sindromul antifosfolipidic şi lupusul eritematos sistemic. Diagnosticul şi tratamentul bolilor autoimune legate de existenţa unei HVC cronice au devenit de primă importanţă în preocupările specialiştilor, având în vedere prognosticul sumbru al acestor pacienţi. Deşi scopul tratamentului antiviral este ţintit pe afectarea hepatică primară, există suficiente date asupra eficienţei şi siguranţei utilizării acestor terapii la pacienţii care prezintă manifestări extrahepatice asociate. Managementul adecvat al acestor pacienţi trebuie axat pe două direcţii : eradicarea sau reducerea încărcăturii virale (terapia convenţională antivirală) şi tratamentul manifestărilor autoimune (corticosteroizi, plasmafereză, agenţi citotoxici) (2,5,6). Pe lângă manifestările extrahepatice enunţate în literatură, anumite comorbidităţi (care nu pot fi încadrate în acest grup) trebuie avute în vedere atunci când se instituie tratamentul specific, anti-

viral sau corticosteroid. Patologia asociată este un element important în evaluarea bolii, atât în ceea ce priveşte evoluţia pacientului care urmează sau a urmat un anumit tratament, cât şi în estimarea necesităţii instituirii unei anumite terapii sau în ceea ce priveşte oportunitatea modificării liniei terapeutice.

Tratamentul infecţiei cronice HVC cuprinde monoterapia cu IFN alfa sau asocierea acestuia cu Ribavirinul. Utilizarea acestora la bolnavii cu manifestări extrahepatice este controversată, pe de o parte, datorită excluderii acestor pacienţi din trialurile multicentrice (4), iar pe de altă parte, lipsei răspunsului la tratament sau apariţiei unor efecte secundare grave care au impus, în final, abandonarea terapiei. Există, totuşi, date care să ateste o oarecare eficienţă a tratamentului antiviral asupra HVC cronică cu determinări extrahepatice. Interferonul alfa s-a dovedit a fi eficace la unii pacienţi cu crioglobulinemie, mai ales la cei la care viremia ARN-VHC devine nedetectabilă în ser. Totodată, trebuie avută în vedere o monitorizare strictă a terapiei, din punctul de vedere al efectelor secundare imediate sau la distanţă. Noul IFN pegylat este superior ca şi eficacitate, dar şi prin incidenţa mai mică a efectelor secundare. Ribavirina, utilizată în monoterapie sau asociată cu IFN alfa, ar putea fi eficace şi în tratamentul crioglobulinemiei asociate HVC, însă utilizarea acesteia la pacienţii cu manifestări renale trebuie atent monitorizată. Missiani et al a dovedit că ribavirina poate avea efecte secundare severe, cum sunt anemia şi rashul pruriginos, care pot determina întreruperea terapiei.

În ceea ce priveşte utilizarea corticosteroizilor, există puţine date care să ateste eficacitatea la pacienţii cu HCV cronică. Unii autori au observat creşterea viremiei în timpul tratamentului, reversibilă la întreruperea terapiei. Thyele et al. a găsit un răspuns favorabil la corticosteroizi, mai ales în cazul asocierii cu azathioprina. De asemenea, tratarea pacienţilor cu VHC şi manifestări extrahepatice cu agenţi imunosupresivi este controversată. S-au observat rate crescute de morbiditate şi mortalitate la cei care au primit tratament imunosupresiv, probabil şi datorită severităţii bolii hepatice sau extrahepatice (5).

Liniile directoare de tratament sunt bine stabilite la adulţi. La aceşti pacienţi, studiile actuale au scopul de a se putea scurta durata tratamentului (la 16 săptămâni, în cazul unui genotip sensibil, şi la 24 de săptămâni, în cazul genotipului 1) pentru subiecţii cu răspuns virusologic rapid, şi de a prelungi terapia (48 săptămâni pentru genotipul 3 şi 72 săptămâni pentru genotipul 1) pentru subiecţii care înregistrează o scădere a viremiei, dar cu persistenţa ARN VHC pozitiv în săptămâna 12. Alte investigaţii în curs de desfăşurare au ca scop creşterea eficacităţii tratamentului prin adăugarea de agenţi cum ar fi telaprevir sau boceprevir, la tratamentul convenţional PEG-IFN plus ribavirină.

La copil, formele severe de boală sunt rare, însă este necesară urmărirea periodică. Terapia antivirală nu atinge ratele de creştere a eficienţei răspunsului în comparaţie cu pacienţii adulţi, însă efectele adverse sunt mai frecvente la copil şi, în unele cazuri, pot fi severe. Ţintele tratamentului HVC cronică la copil sunt reprezentate de normalizarea pe termen lung a transaminazelor, obţinerea unui răspuns virusologic susţinut, oprirea sau întârzierea degradării histologice hepatice, scăderea riscului de apariţie a cirozei şi a carcinomului hepatocelular, astfel că decizia de a trata ar trebui să ia în considerare mai multe aspecte, individualizate pentru fiecare pacient în parte (vârsta, gravitatea bolii, eficacitatea tratamentului ales, efectele sale negative, estimarea complianţei la tratament).

În prezent, utilizarea de PEG-IFN cu ribavirină, care a fost aprobat de FDA din SUA (în decembrie 2008) şi EMEA (în de-

cembrie 2009) pentru copiii mai mari de 3 ani reprezintă gold-standardul terapiei HCV cronice. Criteriile pentru eligibilitate sunt : vârsta 3-18 ani la momentul înregistrării, viremia VHC (orice metodă) detectabilă în 2 momente diferite, la distanţă de cel puţin 6 luni, boala hepatică cronică, indicată de inflamaţie şi/sau fibroză, boala hepatică compensată (Child-Pugh Grade A clinical classification), consimţământ informat semnat de părinte / susţinător legal, hemoglobina > 11 g/dL pentru fete ; > 12 g/dL pentru băieţi , TSH normal.

Rămâne de stabilit prin studii ulterioare profilul de siguranţă şi eficacitate al acestei terapii, precum şi influenţa asupra prezenţei şi a dezvoltării manifestărilor extrahepatice.

STUDIUL PERSONAL

Ideea acestui studiu a plecat de la necesitatea evaluării corecte a patologiei asociate manifestărilor extrahepatice în hepatitele cronice ale copilului, atât din necesităţi de certitudine a etiologiei, cât şi terapeutice. Unele dintre aceste afecţiuni apar independent de existenţa suferinţei hepatice de bază, însă pot influenţa starea clinică a pacientului, unele date biologice, precum şi calitatea vieţii, astfel încât se impune investigarea, tratarea şi urmărirea lor pe termen lung. Lipsesc studiile la copil legate de incidenţa, gravitatea şi semnificaţia acestor manifestări la copil.

În acest sens, am stabilit următoarele obiective :

- evaluarea incidenţei manifestărilor extrahepatice în hepatita cronică VHC la copil ;
- evidenţierea tipurilor şi subtipurilor de manifestări extrahepatice întâlnite în practică, în comparaţie cu datele furnizate de literatura de specialitate ;
- urmărirea influenţei pe care aceste manifestări extrahepatice o au în evoluţia bolii şi asupra calităţii vieţii acestor pacienţi ;
- asocierea manifestărilor extrahepatice cu alte stări patologice şi evaluarea evoluţiei naturale şi/sau sub impactul terapiei specifice (antivirale) şi nespecifice (hepatoprotectoare, hipocolesterolemiante, antibiotice etc.) asupra acestor afecţiuni şi asupra patologiei de bază.

MATERIAL ŞI METODĂ

Lotul luat în studiu a cuprins 43 de pacienţi diagnosticaţi şi urmăriţi în Clinica Pediatrie II Iaşi cu diagnosticul de hepatită cronică VHC în perioada ianuarie 2005 - iunie 2010. Distribuţia zonală a acestora a fost de 60,5% mediul urban şi 39,5% mediul rural, iar pe sexe 67,44% masculin şi 32,55% feminin. Majoritatea copiilor au provenit din mediul familial, doar unul dintre ei fiind instituţionalizat. Ca modalităţi de infectare, 3 cazuri (6,97%) au fost certificate ca fiind urmarea transmiterii verticale de la mamă, intervenţiile chirurgicale fiind incriminate în alte 3 cazuri, în restul cazurilor neputându-se preciza cauza infecţiei. Diagnosticul de hepatită cronică s-a realizat pe baza criteriilor clasice, iar anamneza a adus informaţii privind etiologia şi debutul infecţiei hepatitice. Examenul clinic efectuat la fiecare control în clinică şi examinările paraclinice şi histologice (puncţia hepatică, Fibroscan) efectuate în timpul urmăririi cazului, au ilustrat, deasemeni, prezenţa suferinţei hepatice cronice şi, la unii pacienţi, a manifestărilor extrahepatice şi/sau a patologiei asociate.

S-au efectuat analize paraclinice la momentul diagnosticului şi/sau intrării în studiu, pe parcursul evoluţiei, înainte şi după administrarea terapiei : hematologice (leucocite, hemoglobina, trombocite), teste hepatice (transaminazele, proteinele totale şi fracţiunile proteice, timpul de protrombină, bilirubina totală şi directă), autoanticorpii (antinucleari, antimitocondriali, anti muşchi neted), factorul reumatoid, crioglobulinele, celulele lupice. Pentru fiecare pacient valo-

rile obţinute au fost încadrate în funcţie de vârsta pacientului în valori crescute, valori normale sau valori scăzute. Analiza acestor rezultate s-a făcut în funcţie de valoarea medie şi de încadrarea în grupele respective. Markerii virali analizaţi au fost anticorpii anti-HCV şi viremia ARN-VHC. Ca investigaţii histologice, puncţia biopsie hepatică a fost efectuată la pacienţii diagnosticaţi şi trataţi înainte de 2008, ceilalţi au beneficiat de metodele Actitest şi Fibroscan.

În funcţie de tratamentul administrat, cei 43 de pacienţi luaţi în studiu au fost grupaţi în următoarele loturi : tratament cu interferon (12 pacienţi, 27,9%), tratament cu interferon şi Ribavirin (1 pacient, 2,32%), tratament cu Pegasys şi Ribavirin (2 pacienţi, 4,64%), tratament hepatoprotector (29 de pacienţi, 67,44%).

REZULTATE

La pacienţii infectaţi, viremia a fost peste 2 milioane de copii virale la 30% cazuri, între 1-2 milioane de copii virale în 60% cazuri, iar la 10% dintre copii a însumat între 600.000-1.000.000 de copii virale.

Diagnosticul de hepatită cronică VHC la pacienţii din lotul studiat s-a făcut, în majoritatea cazurilor, întâmplător sau cu ocazia unor determinări biologice cu valori anormale (transaminaze crescute, markeri virusologici pozitivi pentru hepatita virală tip C).

Frecvenţa manifestărilor extrahepatice a fost de 41,86%, acestea fiind raportate la 18 pacienţi, cele mai frecvente fiind de ordin articular (artralgii în 4 cazuri) şi dermatologic (urticarie cronică şi pitiriazis versicolor, 3 pacienţi). Manifestările hematologice (6 pacienţi cu anemie şi 3 cu trombocitopenie), precum şi depresia severă (2 cazuri) s-au raportat în cadrul tratamentului cu IFN alfa. Aceste estimări se încadrează în datele furnizate de literatura de specialitate, având în vedere că manifestările de ordin articular, cutanat şi hematologic sunt cele mai frecvente, în special la pacienţii cu hepatită cronică de tip viral.

Explorările hematologice, biochimice şi imunologice au arătat diferenţe statistice semificative în ceea ce priveşte nivelul mediu al hemoglobinei (12,2 mg/dL faţă de 14,2 mg/dL la cei fără manifestări extrahepatice, $p=0.000053$) şi al trombocitelor ($204.000/mm^3$ faţă de $232.000/mm^3$, $p=0.010021$). Diferenţele observate în nivelul transaminazelor la cei cu manifestări extrahepatice, cu valori de aproximativ 2 x valoarea normală sunt nesemnificative statistic.

Ca şi patologie asociată, remarcăm prezenţa steatozei cu obezitate şi hipercolesterolemie la 8 pacienţi (18,6%), a gastritei cu sau fără esofagită la 3 pacienţi (6,97%), a colemiei Gilbert la 4 cazuri (9,3%), a osteopeniei la 5 pacienţi (11,62%), a spasmofiliei la 11 pacienţi (25,58%) şi a urticariei la un pacient (2,32%). Pacienţii cu steatoză au răspuns mai puţin la tratamentul antiviral, fără a arăta îmbunătăţiri semnificative.

TRATAMENTUL CU INTERFERON, MANIFESTĂRILE EXTRAHEPATICE ŞI PATOLOGIA ASOCIATĂ

Manifestările articulare şi cutanate au evoluat independent de prezenţa tratamentului specific antiviral, nefiind observate ameliorări semnificative ale simptomatologiei, din datele obţinute de la pacienţi. Manifestările de ordin hematologic, în principal trombocitopenia (cu valori minime de 44000 tr/mm^3), au apărut după tratamentul cu Interferon la 3 (6,97%) din pacienţii trataţi, faţă de doar un caz cu valori plachetare la limita inferioară a normalului înainte de iniţierea tratamentului. Anemia s-a înregistrat la 6 dintre pacienţii trataţi (13,95%), fiind asociată sau nu cu leucopenia şi tombocitopenia, cu valori între 9,1 şi 11 mg/dL. De asemenea, s-a înregistrat un caz care a evoluat spre anemie aplastică, după finalizarea terapiei antivirale. Trebuie menţionată şi depresia, care a apărut la 2

(4,65%) din pacienţii incluşi în lotul de studiu.

S-a observat că tratamentul gastritei (cu sau fără prezenţa *H. pylori*) a ameliorat citoliza hepatică înregistrată concomitent la cei mai mulţi din pacienţii incluşi în studiu, această patologie fiind decelată cel mai frecvent. Numai la unul dintre cei 3 pacienţi diagnosticaţi s-a putut corela prezenţa gastritei şi a sindromului dispeptic cu tratamentul antiviral efectuat anterior cu Interferon alfa.

CONCLUZII

1. La copil manifestarile extrahepatice în hepatita C sunt mai rare decât raportările din literatură la adult, cu preponderenţa celor de ordin articular.
2. În unele cazuri, Interferonul declanşează sau poate agrava unele manifestări extrahepatice cu mecanism imun (în principal manifestările de tip cutanat), ceea ce face ca atenţia îndreptată acestor situaţii să fie crescută, sau chiar să impună reconsiderarea opţiunilor terapeutice. Aşadar, este necesară o evaluare cât mai corectă a pacienţilor înaintea administrării tratamentului cu Interferon pentru a evita apariţia sau agravarea unor manifestări preexistente. Este esenţial să se cerceteze toţi markerii de autoimunitate înaintea terapiei antivirale.
3. Putem aprecia faptul că manifestările hematologice sunt cele mai frecvente din manifestările extrahepatice apărute ca urmare a tratamentului antiviral cu Interferon, dar şi că întreruperea terapiei nu influenţează semnificativ evoluţia manifestărilor extrahepatice, reversibilitatea acestora fiind evidentă doar în cazul depresiei.
4. De remarcat este faptul că existenţa gastritei sau esofagitei nu s-a corelat cu durata bolii sau cu tipul de tratament antiviral urmat, fibroscopia digestivă superioară fiind efectuată la aceşti pacienţi datorită acuzelor subiective de tip anorexie, dureri epigastrice, pirozis.
5. În ceea ce priveşte tratamentul specific al hepatitei cronice, cu antivirale de tipul Interferonului, pot apărea situaţii în care curba ponderală se modifică, în sensul crescător sau descrescător. În literatura de specialitate nu s-a citat o legătură evidentă între excesul ponderal sau obezitate şi hepatita cronică la copil, însă uneori se pot stabili corelaţii ale creşterii curbei ponderale prin manifestări de tip bulimic (acestea putând apărea în urma tratamentului specific antiviral). În studiul nostru s-a remarcat o evoluţie favorabilă a obezităţii, cu scăderea curbei ponderale şi a indicelui de masă corporală la unii pacienţi care au primit tratament antiviral cu Interferon alfa, în unele cazuri scăderea în greutate corelându-se şi cu scăderea gradului de steatoză hepatică decelată ecografic.
6. Prezenţa steatozei hepatice la copiii cu hepatită cronică cu VHC poate fi explicată de dislipidemie în majoritatea cazurilor. În aproape o treime din cazuri însă, steatoza pare cauzată de prezenţa infecţiei cronice VHC, ca factor limitant în ceea ce priveşte tratamentul şi cu un posibil rol favorizant asupra apariţiei fibrozei hepatice. Deşi steatoza nu influenţează semnificativ răspunsul virusologic susţinut, prevenirea şi corecţia obezităţii la copil pot avea un rol important în ameliorarea prognosticului acestor pacienţi.
7. Tratamentul optim al manifestărilor extrahepatice şi al patologiei asociate hepatitelor cronice rămâne în discuţie, datorită datelor insuficiente care să ateste eficacitatea terapiilor utilizate. Se impune, astfel, necesitatea elaborării unor ghiduri terapeutice care ar trebui bazate în principal pe partea simptomatică, de vreme ce patogenia acestor manifestări rămâne incertă. Oricum, atât terapia

antivirală, cât şi cea imunosupresivă şi plasmafereza şi-au dovedit utilitatea, cu toate că administrarea lor în monoterapie sau în combinaţie comportă riscuri. Exacerbarea manifestărilor autoimune trebuie monitorizată atent, atât înainte, în timpul, cât şi la terminarea tratamentului. Se impun, aşadar, cuantificarea funcţiei renale şi a viremiei pe toată perioada administrării terapiei. De asemeni, tratamentul trebuie individualizat, în funcţie de eficacitate, eligibilitate, cost şi riscuri, putând fi recomandat şi susţinut în cazurile când beneficiul depăşeşte aceste piedici.

CARDIOPULMONARY STRESS TEST PERFORMANCE IN PATIENTS WITH MODERATE-SEVERE OBSTRUCTIVE SLEEP APNEA (Abstract): **Introduction**: Cardiopulmonary stress test (CPET) is an important part of risk stratification and prognostic assessment of a cardiovascular patient. Since obstructive sleep apnea (OSA) is a frequent finding in patients with cardiovascular and metabolic comorbidities, the role of CPET in the evaluation of patients with sleep disordered breathing is a subject of great interest. **Aim:** To illustrate the role of CPET evaluation in OSA patients, before and after noninvasive ventilation. **Material and methods**: We performed a prospective study that included 27 patients with newly diagnosed moderate-severe OSA (apnea hypopnea index (AHI) ≥ 15) who underwent a cardiopulmonary stress test before and after 2 months of continuous positive airway pressure (CPAP therapy). We compared baseline CPET performance between OSA patients and 27 age and BMI matched controls. **Results**: OSA severity was not significantly correlated with any of the analyzed baseline CPET parameters. CPET performance did not significantly differ between controls and patients with moderate-severe, moderate or severe OSA. Eight weeks of CPAP therapy lead to a significant improvement in weight status and several CPET parameters, including effort capacity (maximal and percent predicted load), oxygen pulse and percent-predicted oxygen uptake. **Conclusions**: Age, but not AHI, influence baseline CPET results. Although we did not find significant differences between CPET performance in OSA patients and controls, 2 months of CPAP therapy was associated with a significant improvement in exercise tolerance and CPET parameters, suggesting that OSA negatively impacts exercise tolerance. **Keywords**: OBSTRUCTIVE SLEEP APNEA, CARDIOPULMONARY EFFORT TEST, CONTINUOUS POSITIVE AIRWAY THERAPY.

Repetitive total or partial collapse of upper respiratory tract occurring in obstructive sleep apnea (OSA) causes oxygen desaturation, micro-awakenings and daytime sleepiness (1). OSA induces sympathetic activation, oxidative stress, endothelial dysfunction and activation of the angiotensin-aldosterone system, explaining the frequent association of cardiovascular and metabolic comorbidities in OSA patients (1-3).

Cardiopulmonary exercise testing (CPET) is a useful instrument in cardiovascular rehabilitation, as it is able to discriminate between the three potential causes of

exercise limitation: pulmonary, cardiac or muscular dysfunction (3). CPET evaluation is indicated for risk stratification and prognostic assessment in patients with heart failure, ischemic heart disease, pulmonary hypertension (4), but recent reports have emphasized the potential benefit of cardiopulmonary exercise evaluation in OSA subjects. Impaired muscle energy metabolism caused by nocturnal hypoxemia (5), the frequent association of obesity, as well as impaired stroke volume (6) and diminished effort ventilation (7) contribute to exercise limitation in OSA patients. Previous reports regarding CPET performance in obstructive sleep apnea are inconsistent: some studies report a reduced exercise tolerance (7-11), while others state that exercise capacity is not affected by OSA (12-15). However, various studies have shown that even short-term continuous or bi-level positive airway pressure (CPAP or BiPAP), the current gold standard therapy option for moderate-severe OSA (16), is able to improve both symptoms and exercise performance in OSA patients (3, 17-19). The purpose of this study is to illustrate the role of CPET testing in OSA patients admitted in a cardiovascular rehabilitation setting, before and after CPAP therapy.

MATERIAL AND METHODS

We performed a prospective study including patients with newly diagnosed moderate-severe OSA (apnea hypopnea index (AHI) $\geq$ 15), diagnosed using cardiorespiratory polygraph. Recruited were 27 subjects who underwent peak or symptom limited cardiopulmonary stress test, performed before and after 2 months of CPAP therapy. Three patients did not tolerate CPAP therapy and another subject did not return for the second clinical evaluation. Average CPAP use was 4 hours. We compared the baseline CPET results of our OSA patients with that of 27 controls (matched for age, BMI and sex) and also with the results of CPET reevaluation, performed after 8 weeks of CPAP in our OSA group.

Statistical analysis was performed in *SPSS 20.0.* Chi square and student's t test were used for comparisons between groups. The existence of a relationship between variables was evaluated using Pearson correlation coefficient. Descriptive data is presented as mean ± standard deviation, as appropriate. A p value <0.05 was considered statistically significant.

RESULTS

Our sleep apnea group included 11 subjects with moderate and 16 patients with severe OSA (average apnea hypopnea index-AHI 23.57 and 56.03, respectively) (tab. I).

No serious complications were observed during CPET testing in our OSA and control groups. Four OSA patients and four controls stopped the test at submaximal ventilation due to dyspnea, muscle tiredness or elevated BP (>220/120 mmHg). CPET parameters did not significantly differ between our control and OSA groups (Table II) or between controls and patients with severe or moderate OSA, respectively ($p>0.05$).

Although AHI was not significantly correlated with any of the analyzed baseline CPET parameters, we found significant negative correlations between age and basal metabolic rate, maximal effort, peak oxygen uptake (VO_2), anaerobic threshold (AT), minute ventilation (VE) and peak heart rate (HR) (tab. III).

TABLE I

Descriptive statistics – OSA group

	OSA	Moderate OSA	Severe OSA
N	27	11	16
M:F ratio	20:7	7:4	13±3

*analysis performed on the 23 subjects included in our second evaluation

CPAP – continuous positive airway pressure; CPET – cardiopulmonary effort test; BMI – body mass index; VO_2 – oxygen uptake; AT – anaerobic threshold; max – maximum; VE – minute ventilation; HR – heart rate; O_2 – oxygen; SBP – systolic blood pressure; DBP – diastolic blood pressure; RER – respiratory exchange ratio.

DISCUSSION

Previous studies on CPET performance in OSA patients have yielded contradictory results. Lin *et al*. (9) found that overweight patients with moderate-severe OSA present significantly impaired workload, VO_2, AT, maximum VE and oxygen pulse when compared to matched controls. Another report conducted on a larger number of subjects (42 patients and 50 controls) with morbid obesity found a significantly lower weight-indexed VO_2 max in OSA patients compared to controls, as well as a significant negative correlation between AHI and VO_2 (11). The authors also report higher DBP values and decreased HR rise and recovery during and immediately after exercise in OSA patients (11). A correlation between OSA severity and BP increase during exercise, but no significant difference regarding peak VO_2 and VE between patients with mild-moderate and severe OSA have been reported by Przybylowski *et al*. (7), who performed CPET in 111 obese OSA patients. A more recent study found a significant correlation between OSA severity and percent predicted peak VO_2 (8), and Stavrou *et al*. (10) not only show that moderate-severe OSA is associated with reduced peak VO_2 and exercise duration, but also propose a predictive model that differentiates controls from OSA patients with 78% accuracy.

Most studies demonstrating that OSA is

associated with impaired exercise capacity have analyzed obese or overweight individuals. Rizzi *et al*. (12) compared CPET results between norm ponderal OSA patients and controls and found no statistically significant difference concerning peak VO_2, AT and RER. These results can be influenced by a relatively low AHI in the studied OSA population (15.4±9.2) and by the fact that males are greatly underrepresented in the analysis (37%) (12). Another study (13) compared CPET performance in lean and obese patients, with and without OSA, respectively, and found obesity to be the most important factor leading to impaired exercise and ventilatory capacity (illustrated by VO_2 and VCO_2). Despite an altered HR and ventilatory response to exercise, Hargens *et al*. did not find a significant difference regarding VO_2 between young males with OSA and controls (14, 15).

Previous studies of CPAP therapy effect on CPET performance have been conducted on a limited number of subjects. The study of 31 subjects with severe OSA (average AHI 54.25) but with anthropometric characteristics comparable to those of our group (M:F ratio 27:4, average age 53.41, BMI 31.43) reported improved work peak (Δ=16.9W) and percent-predicted-oxygen uptake (Δ=7.6%), but also positive changes in HR reserve (Δ=-6.8%), maximal HR (Δ=6.7 bpm) and VE (Δ=10.3 l/min) after 8 weeks of CPAP therapy (3). Similarly, after 2 months of CPAP therapy, our OSA group presented a significant increase in maximum and percent-predicted-maximum load. Although in our analysis peak oxygen uptake and anaerobic threshold did not significantly improve after CPAP ($p>0.05$), oxygen pulse and percent-predicted-oxygen-consumption exhibited a statistically significant improvement.

Other authors (17) found that 2 month-CPAP therapy improves not only CPET parameters (VO_2, oxygen pulse, work peak, AT and VE) but also BP values and right ventricular ejection fraction, suggesting that the benefits are due to an improvement of overall fitness and cardiac function (17). Goel *et al*. (18) also reported that exercise duration, maximum load, VO_2, oxygen pulse, AT and VE show a statistically significant improvement after 4 weeks of CPAP. However, the analysis included only a small number of subjects (15 patients and 5 controls) and the authors did not compare baseline CPET results between OSA subjects and controls (18). Our patients also presented a small but statistically significant weight loss and a decrease in resting heart rate, but no significant changes in resting and peak blood pressure values.

An interesting study showed that noninvasive ventilation prevents impairment of exercise capacity (decrease in VO_2, workload and AT) in compliant versus non-compliant OSA patients (19). Surprisingly, the analysis showed a decrease in maximal VE among compliant patients (Δ=-6,4 l/min). The authors consider that the short duration of CPAP therapy (42 days) could explain the lack of significant improvement in the analyzed CPAP-compliant group (19).

In another report, 15 obese patients presented no significant improvement in peak VO_2, workload, HR, oxygen pulse or ventilation after 3 months of CPAP (20).

Although our study failed to illustrate a significant difference in baseline CPET results between OSA patients and controls, we found that 2-month CPAP therapy improves several exercise-related parameters. The lack of association between AHI and CPET results can be explained by the fre-

quent association of cardiovascular comorbidities (impaired glucose metabolism – 59.25%, grade 3 hypertension 66.66%, obesity-77.77%) and the high prevalence of former or current smokers (62.96%) in our OSA group. Other limitations of our study are the diagnosis of OSA using cardiorespiratory polygraphy instead of polysomnography and the lack of screening for OSA in our control group. Polygraphy is an accepted alternative to standard polysomnography in the diagnosis of OSA, its major disadvantage being a potential underestimation of OSA severity, which does not interfere with the basic methodology of this study (21, 22).

CONCLUSIONS

Our study showed that some baseline CPET results are influenced by age, but not by OSA severity. The lack of statistically significant correlation between AHI and CPET performance can be explained by the small number of patients included in our analysis as well by the presence of various cardiovascular comorbidities in our OSA group. However, the fact that CPAP therapy was able to effectively improve several CPET variables in our patients shows that sleep apnea negatively impacts exercise tolerance. Further studies are required in order to determine the usefulness of CPET in the monitoring of OSA patients.

NEWS

PRENYLATED COMPOUNDS FROM LEGUMES INDUCE ANTIBACTERIAL AND MEMBRANE PERMEABILIZATION OF *LISTERIA MONOCYTOGENES* AND *ESCHERICHIA COLI*

Under (a)biotic stress, plants from Fabaceae family, produce prenylated phenolic compounds as a defense mechanism, which have shown very good antibacterial activity.Aim of the study: To study the antibacterial proprieties and the effects on the permeability of the bacterial membrane. Materials and methods: *L. angustifolius, A. hypogaea* and *G. max* under-went germination, CC extraction, RP-UHPLC-UV-MS analysis, antibacterial susceptibility and cell membrane permeability tests using fluorescent propidium iodine. Results: Pools contained 165-350 mg prenylated phenolics/g. Chain prenylated isoflavones (cIsf, *L. angustifolius*) were the most active against *L. monocytogenes* (10 μ/ml) compared to controls. None of the pools showed activity against *E. coli* alone. However, cIsf realized the most efficient permeabilization in combination with efflux pump inhibitor (EPI) PaβN, in a dose-dependent manner. Conclusion: Co-administration of prenylated isoflavones with EPI in-creased bacterial membrane permeabilization and antimicrobial effect has been shown. Further experiments with different phenolic classes are necessary to confirm the antibacterial activity (Carla Araya-Cloutier, Jean-Paul Vincken, Roan van Ederen et al. Rapid membrane permeabilization of Listeria monocytogenes and Escherichia coli induced by antibacterial prenylated phenolic compounds from legumes. *Food Chemistry* 2018; 240: 147-155).

OBSTRUCTIVE SLEEP APNEA (OSA) SYNDROME AND TRAFFIC ACCIDENTS (Abstract): For many years traffic accidents represent an important concern in the world and was proven that excesive sleepiness, decreased vigilance of falling asleep in traffic are involved in many car accidents. **Aim**: To asses the correlation between obstructive sleep apnea (OSA) syndrome severity, the lenght of nocturnal arterial oxygen desaturation period and the patients' answers to the Epworth Sleepiness Scale Questionnaire (ESS) and Berlin Questionnaire (BQ). **Material and method**: We used the records of patients admited in Iaşi Pneumology Clinical Hospital with obstructive sleep apnea syndrome between 2007-2008, including only those patients which drive the car daily and excluding those patiernts with comorbidities which could increase the nocturnal arterial oxygen desaturation. The study group (33 patients) have been assessed through polysomnography and some specific questions from ESS and BQ. We identified those patients involved in traffic accidents due to sleepiness. The correlation between obstructive sleep apnea syndrome severity (reflectd by Apnea-Hipopnea Index - AHI), the lenght of the nocturnal arterial oxygen desaturation period ($<90\%$) and the answers the answers to ESS and BQ were assessed. **Results**: Two patients presented mild severity sleep apnea syndrome, 15 presented moderate severity and 16 high severity sleep apnea syndrome. The correlation of AHI with ESS ($r=0,59$, $p<0.001$) and BQ ($r=0.47$, $p<0.05$)were significant while the correlation with nocturnal arterial oxygen desaturation period had no significance ($r=0.29$, $p<0.05$). **Conclusion**: Patients with moderate or severe OSA present a high degree of diurnal sleepiness which could affect the driving capacity. **Key words**: SLEEP APNEA SYNDROME, POLYSOMNOGRAPHY, TRAFFIC ACCIDENT

În ultimii ani problema accidentelor de trafic a constituit o preocupare frecventă la nivel internaţional, siguranţa circulaţiei atrăgând atenţia că cele mai multe astfel de accidente se datorează somnolenţei excesive, respectiv adormirii la volan sau reducerii vigilenţei.

În Franţa, Agenţia Naţională pentru Siguranţa Circulaţiei estima că un sfert din accidentele rutiere fatale care au avut loc în anul 2003 au fost direct corelate cu somnolenţa excesivă (SE). Responsabili de SE sunt numeroşi factori: perioadele lungi de nesomn, consumul de alcool, consumul de droguri, anumite medicamente, scăderea cronica a duratei somnului şi tulburările de somn. Cele mai multe tulburări de somn au drept consecinţă SE, iar sindromul de apnee obstructivă în somn (SAOS) este una dintre ele.

SAOS este o afecţiune frecvent subestimată şi subdiagnosticată, care afectează aproximativ 4% din populaţia generală de sex masculin şi aproximativ 2% dintre femei. Aceste procente cresc semnificativ odată cu vârsta, indicele de masă corporală sau conformaţia anatomică a căilor aeriene supe-

rioare. SAOS se caracterizează prin prezenţa în timpul nopţii a pauzelor de respiraţiei, cui o durată de cel puţin 10 secunde, însoţite de scăderea saturaţiei în oxigen cu cel puţin 4% în prezenţa efortului respirator toracic şi abdominal (1). Pe lângă desaturările nocturne, acre au importante consecinte hemodinamice, episoadele apneice sunt însoţite de microtreziri care fragmentează sistematic somnul pacientului, fiind unul din factorii responsabili de instalarea si menţinerea SE. Studii retrospective ce au la baza date subiective şi obiective, au arătat că frecvenţa accidentelor de circulaţie printre şoferii cu SAOS este mai crescută (2,3,4), însă, datorită numărului scăzut de subiecţi incluşi în aceste studii, acestea au fost ţinta numeroaselor critici.

Teran-Santos et al. au raportat într-un studiu (5) existenţa unei asociaţii puternice între SAOS şi riscul de accidente rutiere. Autorii au observat că şoferii care s-au prezentat la camera de gardă după implicarea într-un accident rutier aveau un risc mult mai crescut decât populaţia generală de a fi diagnosticaţi cu SAOS. Relaţia dintre SAOS şi accidentele rutiere rămâne semnificativă chiar după ajustarea potenţialilor cofactori : consumul de alcool, vârsta, indicele de masă corporală, experienţa ca şofer, utilizarea medicamentelor care au ca efect secundar somnolenţa sau antecedentele de accidente de circulaţie. Rezultatele acestor studii confirmă că rata accidentelor de trafic la persoanele cu SAOS este de 3-4 ori mai mare decat la cele care nu au această boală (6,7, 8). Tratamentul corect al acestei afecţiuni reduce riscul de a adormi, creşte rezulatele obţinute la testele de performanţă şi vigilenţă şi scade numărul accidentelor raportate de persoanele cu apnee de somn (8,9,10,11, 12,13).

În laboratorul de polisomnografie al Spitalului Clinic de Pneumologie din Iaşi, posibilitatea testării vigilenţei sau performanţei la pacienţii adresaţi cu suspiciune de SAOS este limitată. Astfel, am corelat datele obţinute de la pacienţii care au fost înregistraţi polisomnografic pentru a estima riscul de scădere a vigilenţei în timpul şofatului. Există date în literatură care corelează hipoxemia nocturnă intermitentă întâlnită la pacienţii cu SAOS cu scăderea vigilenţei. Pentru estimarea subiectivă a somnolenţei diurne excesive aplicăm fiecărui pacient scala de somnolenţa Epworth (Epworth Sleepiness Score--ESS). Akiko N. şi colaboratorii raportau în articolul "*Daytime sleepiness and automobile accidents in patients with obstructive sleep apnea syndrome"* publicat în 1998 existenţa unei corelaţii semnificative pozitive între rezultatele obţinute la evaluarea somnolentei diurne şi riscul de accidente rutiere ($r=0.56$, $P<0.01$). Pacienţii cu afecţiuni repiratorii nonapneice, care se însoţesc de hipoxie cronică prezintă, de asemenea, alterarea funcţiilor cognitive şi scăderea performanţei şi a vigilenţei (14,15).

Scopul acestei lucrări este evaluarea corelaţiilor dintre severitatea SAOS, timpul petrecut la o saturaţie inferioară celei de 90% şi răspunsurile pacienţilor la intrebările caracteristice din chestionarele Epworth şi Berlin (Berlin Questionaire-BQ).

MATERIAL ŞI METODĂ

Am reanalizat fişele pacienţilor care s-au adresat Laboratorului de Polisomnografie din cadrul Spitalului Clinic de Pneumologie din Iaşi pentru suspiciunea de sindrom de apnee în somn în perioada 2007-2008, şi care în urma investigaţiilor au fost diagnosticaţi cu SAOS. Am selectat doar pacienţii care aveau carnet de conducere şi conduceau efectiv maşina ca activitate zilnică. De asemenea, am evaluat numărul pacienţilor care au declarat implicarea într-un eveniment rutier datorat somnolenţei, în absenţa consumului de alcool sau a medicaţiei care să determine SE. Am exclus 1 pacient datorită diagnosticului de SAOS asociat cu narcolepsie şi 7 pacienţi care au

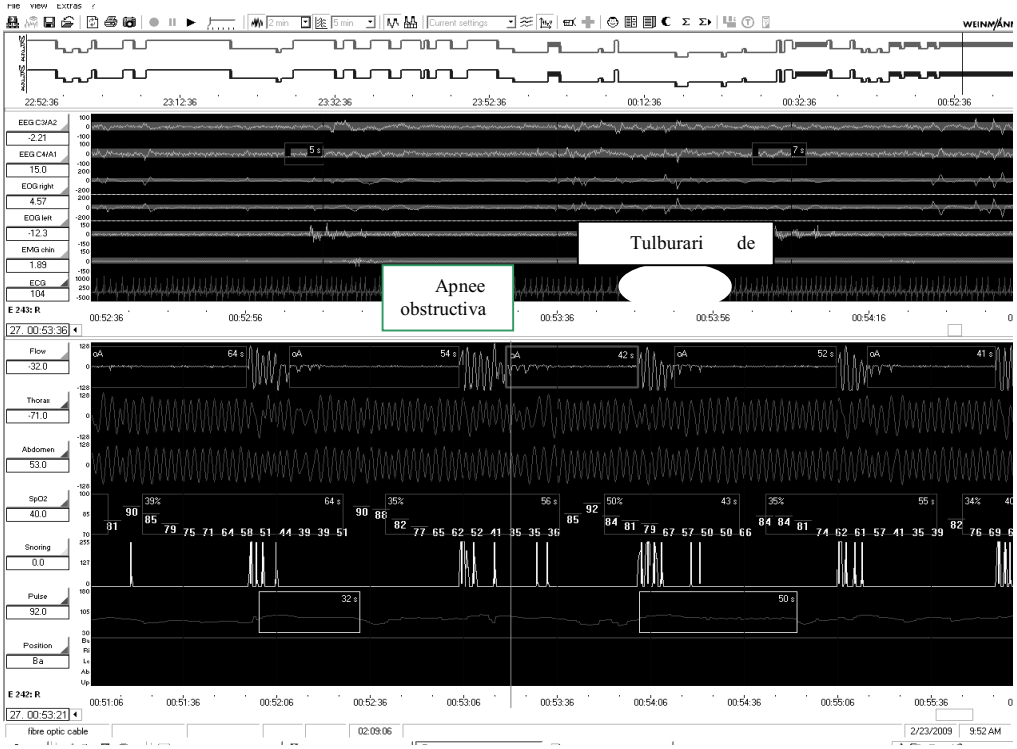

Fig. 1. Imagine dintr-o înregistrare polisomnografică a unui pacient cu SAOS sever

refuzat să completeze întrebările corespunzătoare din ESS si BQ. Au fost excluşi şi pacientii cu comorbidităţi care accentuau desaturările nocturne : 5 pacienţi cu BPOC si 3 pacienţi cu astm bronşic. În final am analizat rezultatele a 33 de pacienţi (6 femei) cărora li s-a indicat polisomnografie completă şi care au fost diagnosticaţi cu SAOS, în toate formele. Toţi pacienţii au completat la internare formularul de consimţământ informat privind utilizarea datelor personale. Pacienţii au fost înregistraţi cu polisomnograf Weinmann Somnolab 1.29, soft SomnoManager 1.3. Polisomnografia completă a constat din inregistrarea următorilor parametri :

a). Parametri neurofiziologici

1. EEG (electroencefalograma) : s-au utilizat două canale, electrozii fiind plasati conform standardelor actuale ale AASM (American Academy of Sleep Medicine, 2007) ;
2. EOG (electrooculograma)
3. Electromiograma muşchilor mentonieri
4. Electromiograma muşchilor pretibiali, pentru un singur membru inferior.

Pentru parametri descrişi la punctele 1-3 s-au utilizat electrozi Grass EEG, iar pentru fixarea acestora s-a utilizat crema EC Grass 2.

b) Parametri cardiorespiratori

1. Electrocardiograma
2. Flux respirator : s-au utilizat fie canula nazală, fie termistorul nazal, care au înregistrat de asemenea şi sforăitul.
3. Saturaţia în oxigen, pulsul periferic şi pletismografia înregistrate prin intermediul pulsoximetrului
4. Efortul respirator toracic şi abdominal : centura toracică şi, respectiv cea abdominală, prevazute cu sisteme piezoelectrice pentru detectarea efortului de întindere.
5. Detector al poziţiei corpului în timpul

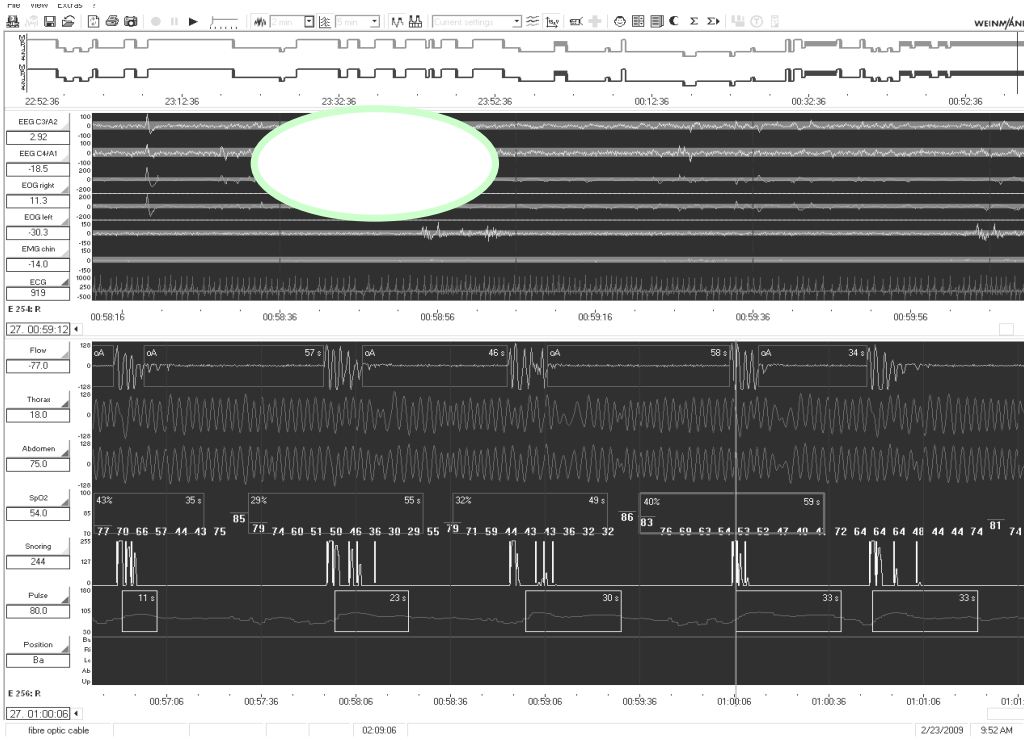

Fig. 2. Microtrezire, stadiul REM. Se observă mişcările în oglindă ale globilor oculari pe electrooculogramă. Severitatea evenimentelor respiratorii este agravată de somnul REM. În imaginea de mai sus, pacientul desaturează până la o valoare a SaO2 de 36%, iar durata apneilor obstructive este în creştere. Evenimentele respiratorii obstructive repetate sunt însoţite de variabilitate cardiacă şi tulburări de ritm

somnului

6. Microfon pentru înregistrarea zgomotelor din camera
7. Camera video, prevazută cu infraroşu, pentru înregistrarea imaginilor în timpul somnului pacientului.

Ora de pornire a înregistrării a fost cuprinsă între 20 : 50 şi 22 : 45, iar ora de întrerupere a înregistrarii a fost între 5 : 30 si 7 : 00.

Fiecare înregistrare a fost analizată pentru determinarea stadiilor somnului, microtrezirilor, mişcărilor periodice ale membrelor, tulburărilor de ventilaţie de tip obstructiv/central/mixt şi desaturărilor conform recomandărilor AASM. Validarea a fost efectuată manual. Astfel, pentru încadrarea nozologică a tulburarilor respiratorii în timpul somnului s-au utilizat următoarele caracteristici :

- Apnee obstructivă : sistarea fluxului respirator (semnal Flow) pentru cel puţin 10 secunde, însoţită de o desaturare de minim 4% şi de menţinerea efortului respirator.

- Hipopnee : reducerea amplitudinii fluxului respirator cu cel puţin 50%, cu o durată de cel puţin 10 secunde şi însoţită de desaturare cu cel puţin 4% faţă de valoarea anterioară. Pe înregistrările polisomnografice, desaturările preced evenimentele obstructive şi se desfăşoară concomitent cu apneile de tip central.

Fişa polisomnografică a pacientului cuprinde datele completate în prezenţa asistentei medicale sau a medicului, ESS şi BQ, datele privind acuzele, tratamentul medicamentos urmat, relaţia cu fumatul, consumul declarativ de alcool, comorbidităţi. S-a măsu-

TABELUL I
Principalele date ale pacienţilor

	Media	DS	Min	Max
Vârsta	46,66	11,86	23	66
AHI	36,15	19,6	13	98
ESS	10,33	2,02	6	14
CT90	47,81	36,07	4	162

rat perimetrul gâtului şi cel abdominal ; s-a calculat indicele de masă corporală (IMC). Datele celor 33 de pacienţi pe care le-am utilizat în aceasta analiză sunt prezentate în tabelul 1 : valorile medii, deviaţia standard, valoarea minimă şi maximă pentru fiecare parametru. Răspunsul la întrebarea „Aţipiţi la volan ? ” din BQ a fost un înregistrat astfel : răspuns pozitiv – 1, răspuns negativ- 0.

REZULTATE

Severitatea SAOS este cuantificată prin indicele apnee-hipopnee pe ora de somn (AHI). Un indice cuprins între 0 şi 5 indică absenţa SAOS, 5 > AHI > 15 indică SAOS uşor, AHI cuprins între 15 şi 30 indică forma moderată a bolii, iar un indice mai mare de 30 indică forma severa de boală. Toate datele pacienţilor au fost introduse în tabele (Microsoft Office Excell, 2003). Pentru analiza statistică s-a utilizat programul de statistică al Office Excell. Corelaţia s-a efectuat cu ajutorul funcţiilor correl, covariance şi coeficientul Pearson.

Din cei 33 de pacienţi 2 au avut SAOS uşor, 15 SAOS moderat şi 16 au avut forma severă de boală.

Astfel, analizand în paralel AHI şi ESS observăm existenţa unei corelaţii pozitive

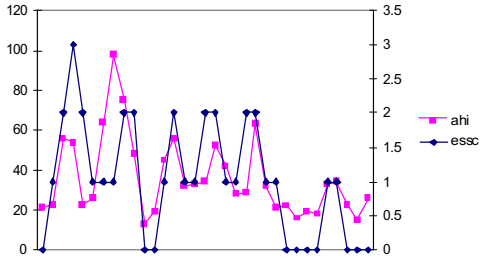

Fig. 4. Relaţia AHI –ESS spec.

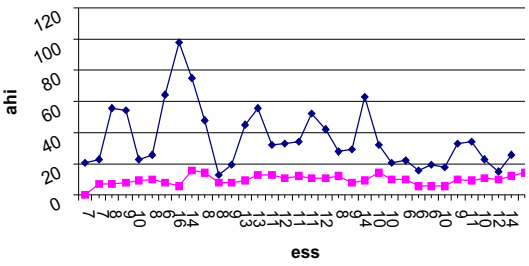

Fig. 3. Relaţia AHI-ESS

semnificative între cei doi parametri (r = 0.59, p < 0.001) (fig. 3).

Aplicând acelaşi procedeu am dorit să vedem dacă se menţine corelaţia şi în cazul răspunsului la întrebarea selectată din ESS (ESSspec). Astfel, indicele de corelaţie dintre AHI şi ESS spec este de 0.59, arătând acelaşi grad de corelaţie puternică pozitivă (fig. 4).

Observăm însă o slabă corelaţie între saturaţia în oxigen din timpul nopţii, în special între timpul petrecut sub valoarea de 90% a SaO2 şi SE (r = 0.29, p < 0.05), lipsită de valoare statistică.

Deşi de tip dihotomic, răspunsul la întrebarea selectată din BQ este strâns legată de severitatea bolii. Observăm pe grafic (fig. 5) că doar o mică parte din pacienţii cu forma moderată şi toţi cei cu forma uşoară de boală răspund „nu” la aceasta întrebare, iar cei cu forma severă de boală şi cei mai multi cu forma moderată răspund „da”.

DISCUŢII

Având în vedere că în lotul ales distribuţia în funcţie de severitatea bolii nu a

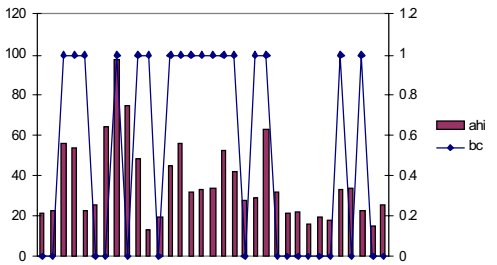

Fig. 5. Relaţia AHI- BQ ; r = 0.47, P < 0.05

fost echitabilă, datorită prezenţei în număr redus al pacienţilor cu forma uşoară a bolii, este necesară verificarea acestor date pe un lot mai mare numeric şi mai bine reprezentat. Numeroasele condiţii pentru ca un pacient să fie inclus în această analiză a limitat sever numărul pacienţilor admişi. Prezenţa copleşitoare a pacientilor cu forma severă de boală la diagnostic este, pe de o parte, meritul unei selecţii atente a pacienţilor, utilizarea diagnosticului în ambulator prin poligrafie cardiorespiratorie ambulatorie, iar pe de altă parte un marker al subdiagnosticării formelor uşoare şi moderate în serviciile de medicină primară.

Modalitatea cea mai simplă de a scădea riscul de accidente datorat SAOS este creşterea vigilenţei asupra acestei boli, ceea ce va duce la creşterea şanselor de identificare şi diagnostic. Acest aspect poate fi realizat prin educaţie, în special privind semnele şi simptomele acestei afectiuni, mai ales că ele sunt usor de recunoscut de anturaj. Deşi diagnosticul SAOS este o problemă rezolvabilă, existând mijloace şi metode bine structurate, nu există posibilitatea ca în urma analizarii polisomnografice, a datelor de laborator cu care se coroborează datele obţinute la polisomnografie, testelor de evidenţiere a SE, testarilor diurne (MSLT, MWT) de a prezice care şofer diagnosticat cu apnee de somn va avea un accident rutier. În acelaşi timp există mulţi pacienţi care fie au evitat în ultimul moment un accident, fie nu au avut unul, astfel că nu se poate pune problema limitării accesului lor la volan. In plus, efectuarea tratamentului aduce rezultate spectaculoase, atât în planul SE şi al vigilenţei cât şi în privinţa comorbidităţilor asociate.

Datele obţinute din analiza prezentată doar deschid drumul către necesitatea administrării altor teste tuturor soferilor care se adresează laboratorului de polisomnografie şi sunt diagnosticaţi cu SAOS. Astfel, se impune evaluarea vigilenţei, fie prin teste de tipul cititului, fie prin testul Osler, fie prin MSLT, însă acesta din urma este foarte consumator de timp şi de resurse. Teste de tipul simulării condusului nu sunt accesibile în laboratorul nostru. Aceste testări trebuie efectuate atat la diagnostic cât şi ca marker al eficienţei tratamentului recomandat.

Deşi hipoxemia nocturnă din afecţiunile respiratorii cronice (BPOC) a fost incriminată în determinarea unor tulburări cognitive şi deficit de atenţie, datele noastre, efectuate pe un lot redus de pacienţi, nu arată acelaşi lucru ca cele din bibliografie.

Începând din 1997 anumite state care au încercat să legifereze necesitatea efectuării polisomnografiei pentru şoferi (16), s-au lovit de reticenţa medicilor în a divulga date care le-ar vătăma relaţia de confidenţialitate pe care o au cu pacienţii.

În 1991, un grup de experţi din Federaţia Transportatorilor Americani recomandau ca şoferii cu suspiciune de SAOS sau cu SAOS netratat să fie consideraţi necalificaţi medical pentru a conduce vehicule comerciale până când fie diagnosticul elimină suspiciunea de SAOS, fie până când sunt trataţi adecvat. Acest grup recomandă ca şoferii trataţi pentru SAOS să-şi continue terapia pe toata durata menţinerii carnetului de şofer profesionist şi să efectueze anual o testare MSLT (16). Aceste reguli însă nu au fost încadrate într-o formă legală, iar recomandările nu au fost incluse în ghidurile medicilor care examinează şoferii profesionişti. În contrast însă, Federaţia Piloţilor are reguli clare în privinţa diagnosticării şi tratării SAOS, fiecare pilot fiind nevoit să efectueze anual o polisomnografie şi un test de menţinere a vigilenţei (MWT). Controale regulate sunt clar specificate pentru a se evalua eficacitatea terapeutică.

CONCLUZII

Pacienţii cu SAOS moderat sau sever prezintă un grad înalt de somnolenţă diurnă excesivă, somnolenţă care se repercutează

şi asupra statutului de şofer. Corelând date subiective privind somnolenţa la volan din chestionarele completate de pacient, cu date obiective, obţinute din înregistrările polisomnografice, putem afirma că SAOS este o afecţiune care alterează gradul de vigilenţă la volan, iar gradul de alterare este corelat puternic cu severitatea bolii. Acest efect nu se datorează exclusiv hipoxiei nocturne ; biciuirea sistematică simpatică a sistemului nervos central şi afectarea calităţii somnului contribuie la somnolenţa din timpul zilei. Rămâne ca pe viitor să verificăm aceste date pe un număr mare de pacienţi, iar datele subiective sa fie corelate cu date obiective, obţinute în urma unor teste standardizate.

WHY 3D ULTRASOUND AND HYSTEROSCOPY SHOULD REPRESENT THE GOLD STANDARD FOR DIAGNOSIS AND MANAGEMENT OF UTERINE OSSEOUS METAPLASIA? CASE REPORT (Abstract): Osseous metaplasia of the endometrium represents a disorder of the uterus characterized by the presence of mature or immature bone in the uterine cavity. In most of the cases infertility or menorrhagia can be present, although sometimes this condition can be asymptomatic. Endovaginal ultrasound and particularly three-dimensional ultrasound are very important diagnostic tools. Hysteroscopic removal of the bony fragments helps in treating both infertility and menorrhagia. We present a case of 28 years-old women with osseous metaplasia and uterine synechia. Three-dimensional ultrasound was useful for the diagnosis and both affections were solved by hysteroscopic approach. **Keywords**: OSSEOUS METAPLASIA, 3D ULTRASOUND, HYSTEROSCOPY.

Osseous metaplasia of the endometrium, represents a rare disorder of the uterus, characterized by the presence of mature or immature bone in the uterine cavity. Although a rare condition, with the increasing use of ultrasound, the condition is being diagnosed more frequently. Osseous metaplasia can induce infertility or menorrhagia. Removal of the bony fragments helps in treating both, infertility and menorrhagia. We present, a clinical case of young women 28-years-old with osseous metaplasia associated with uterine synechia.

CASE REPORT

A G1 P0 28-year-old woman presented, with a history of menorrhagia for two months. She had been married for the last 4 years and had a missed abortion two months ago, after which she underwent dilatation and curettage at 14 weeks gestation. After the abortion, the patient had menorrhagia and the curettage was repeated. Following the second curettage, the patient still had bleeding and another gynecological examination, combined with three-dimensional (3D) acquisition was performed (Voluson E8, endovaginally probe 4-8 Hz, GE Healthcare). Longitudinal and transverse plane sonograms of the uterus revealed multiple hyperechogenic areas, of various sizes within the endometrium, with posterior

acoustic shadowing (fig. 1). The coronal plane of the uterus obtained with 3D ultrasound probe, was useful for the diagnosis, showing the irregular shape of the hyperechoic areas (fig. 2).

Based on these imaging findings and clinical history, a presumptive diagnosis of osseous metaplasia of endometrium was made and a hysteroscopy was performed. The diagnosis was confirmed, many bony fragments were observed and extracted under direct visualization, one of them resembling a long bone of the fetus (fig. 3, 4). Moreover, during hysteroscopy, a uterine synechia was identified and managed by hysteroscopic approach (fig. 5).

After the procedure the metrorrhagia resolved and the menstrual resumed as normal.

Fig. 1. Two-dimensional ultrasound- longitudinal plane of the uterus- hyperechogenic linear structure centrally positioned in the uterine cavity and irregular hyperechogenic structure at the isthmus; both images have posterior acoustic shadowing

Fig. 2. Three-dimensional ultrasound- coronal plane of the uterus- hyperechoic structure in the uterine cavity and at the level of the isthmus

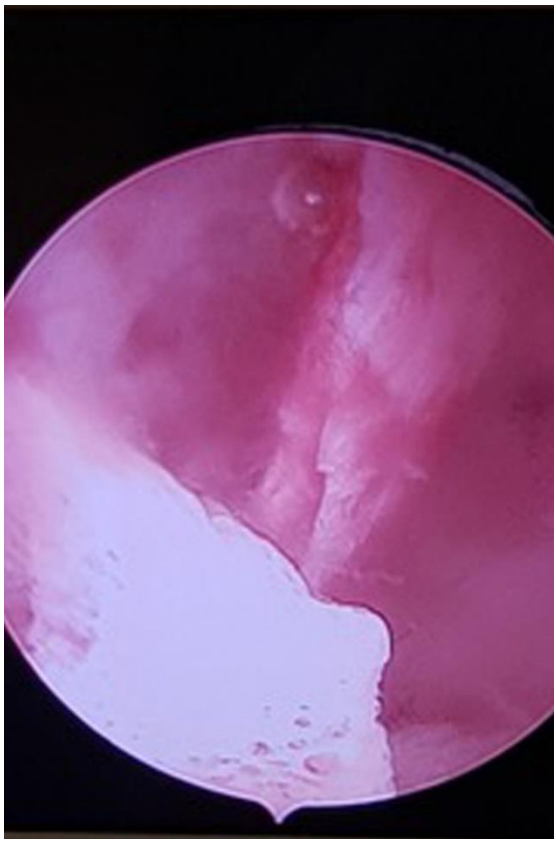

Fig. 3. Hysteroscopic image - bony fragments in the uterine cavity

Fig. 4. Hysteroscopic image- bony fragments in the uterine cavity

Fig. 5. Image of the extracted bony fragments from the uterine cavity.

DISCUSSION

Osseous metaplasia is a rare condition and in literature, between 1928 and 2013 there have been published, a total of 293 patients in 155 case reports and case series (1). In infertile women, the prevalence of osseous metaplasia is estimated to be approximately 0.002% (2). In the general population, the prevalence is unknown but is lower than in infertile women. The number of cases reported increased with the routine use of ultrasound exploration, in gynecology. The condition is also known as ectopic intrauterine bone, heterotopic intrauterine bone and endometrial ossification.

There have been several theories proposed for this condition. The origin of the bone fragments could be either retained fetal bone from prior termination of pregnancy, or osseous endometrial metaplasia. The theory of ossification of fetal residual tissue is sustained by the observation that in almost all cases, patients with endometrial ossification have a past medical history of abortion, ranging from 8 weeks to 37 years prior to the diagnosis of osseous metaplasia (3, 4). In the case of stromal metaplasia, hormonal, chronic endometritis or exogenous stimuli (like intrauterine device) are considered the main triggering factors. In these cases, the process of metaplasia could represent an adaptive change of one cell for another, due to the local adverse environment (5). This theory may explain the few published cases of osseous metaplasia in women with no obstetrical history (6).

Usually, the main complication associated with osseous metaplasia, is secondary infertility. The infertility occurs, because of the osseous fragments, which act like a foreign body and mimics the action of an intrauterine device (IUD). In other cases, osseous metaplasia can cause pelvic pain, dysmenorrhea, and menstrual disorders (7). Osseous metaplasia can sometimes be an incidental finding and may act as an involuntary contraception (8).

The ultrasound examination shows a characteristic pattern in the uterine cavity with linear or irregular hyperechoic images with posterior acoustic shadowing (9, 10,

11). Sometimes these patterns may by misdiagnosed with an IUD. In these cases, 3D ultrasound can be used, because it is a powerful tool that enables us to examine coronal plane of the uterus (12). In osseous metaplasia, in the coronal plane we can clearly view the number, the contour and the position of the osseous material in the cavity.

The differential diagnosis includes the presence of IUCD, foreign bodies, Asherman's syndrome, calcified submucosal fibrosis, and Mullerian tumor (4).

The management should be complete removal of the bony fragments from the endometrial cavity, by hysteroscopy. An alternative is uterine curettage. However, vigorous curettage should be avoided, because sometimes this method cannot ensure the extraction of all the fragments and moreover has the risk of synechiae formation as described in our case.

CONCLUSIONS

Osseous metaplasia is a rare uterine condition that can induce infertility or menorrhagia. Sonographic examination, and in particular 3D ultrasound plays a primary role in the diagnosis. The characteristic ultrasound pattern, a hyperechoic image in the uterine cavity, is strongly suggestive of osseous tissue within the uterus. The ultrasound examination should be confirmed by hysteroscopy, the gold standard for the management of this entity.

MYTH OR REALITY IN "*STARRY NIGHT"* (1889). DID VINCENT VAN GOGH PAINT HIS *MORBUS LOCI* ? WHIRLPOOL GALAXY, HIPPOCAMPAL FORMATION OR JUST A PAINTBRUSH MOVE ? (Abstract): Vincent Van Gogh's entire career has been marked by a variety of colors, which have undergone numerous changes: from gray to vivid colors. This is due to the multiple affections that the author acquires over the course of his life and the treatments adjacent to his affections. A special feature of his artistic life is *tripartite nocturnal series* during the time the artist was admitted to the Saint Paul Asylum. Nowadays this series of paintings are known around the world and listed at exorbitant prices. Much of the paintings made by the artist in the second half of his life have a common element about a representative geometric model, a brush motion. Long after the artist's death, art critics, doctors and ordinary viewers have associated this geometric model with the anatomy of the hippocampus. The previous idea was recently exposed by a group of authors in the article: Neuroanatomic Interpretation of the Painting *Starry Night* by Vincent van Gogh. Our opinion after lengthy analyzes of the artist's biography is that he did not have neuroanatomic knowledge and therefore the theory that Vincent Van Gogh painted his *morbus loci* cannot be sustained. A more likely explanation is that this brush movement (amplified by the pathology suffered by the painter) perfectly corresponds to astronomical elements discovered at that time, *Whirlpool Galaxy* described and drawn first by Sir William Parsons, 3rd Earl of Rosse (1800-1867) in 1845. **Conclusions:** The details given by Van Gogh in the sky of Saint Remy are his visions as a painter and are unrelated to the anatomical structure of the hippocampus. **Keywords:** VAN GOGH, TRIPARTITE NOCTURNE SERIES, STARRY NIGHT, HIPPOCAMPUS, TEMPORAL LOBE, EPILEPSY, WHIRPOOL GALAXY.

Vincent Van Gogh was a Dutch painter of post-Impressionist style. His works have deeply influenced the art of the nineteenth century. A mark of his works is the vivid colors, the wrinkling character of the traces left by the brush and the emotional effect that catches the viewer.

The artist was born March 30, 1853 in Groot-Zundert, in the south of Holland.

A key moment in his artistic career was

the encounter with the French Impressionists in 1886 when he moved to Paris and then to the town of Arles. During this period, he met his friend and collaborator painter, Paul Gauguin (1848-1903), who was to be involved in the enigmatic incident in which Vincent Van Gogh cut off his ear because of mental illness. After this incident, Vincent Van Gogh was admitted to Saint-Remy-de-Provence Hospital for one year, until 1889.

Van Gogh has made over 2,000 works of art, around 900 paintings and 1,100 drawings and sketches. He was little appreciated during his life, his fame grew in the years after his death. Today the artist is considered to be one of the most important painters in history.

Career and artistic masterpiece

His career can be divided into 4 stages: Paris (1886-1888), Arles (1888-1889), Hospital in Arles (December 1888) and the most interesting: Saint Paul Asylum (1888-1889).

In the first period of the artist's life he was focused on portraits and surrounding landscapes, the canvas created by him having a darker tone than the rest of his paintings.

Paris (1886-1888)

In 1886, he went to Paris to join his brother Théo, the manager of Goupil's gallery. In Paris, van Gogh studied with Cormon, inevitably met Pissarro, Monet, and Gauguin. Having met the new Impressionist painters, he tried to imitate their techniques; he began to lighten his very dark palette and to paint in the short brush strokes of the Impressionists' style. Unable to successfully copy the style, he developed his own more bold and unconventional style (fig. 1).

Arles (1888-1889)

At the Yellow House in Arles, van Gogh hoped like-minded artists could create together. Gauguin did join him but with disastrous results. Van Gogh's nervous temperament made him a difficult companion and night-long discussions combined with painting all day undermined his health (fig. 2).

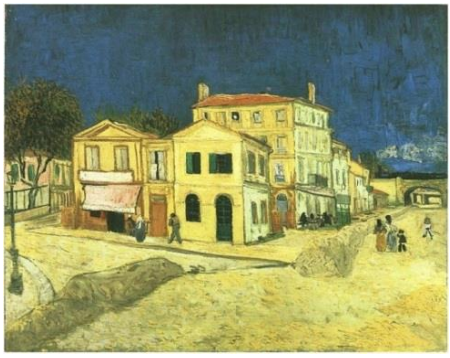

Fig. 2. *The Yellow House*. Vincent van Gogh. Oil on canvas, Arles: September 1888. Van Gogh Museum Amsterdam, The Netherlands, Europe

After the key point of his move to Paris, Van Gogh had a prolific artistic boom: he completed 200 paintings and more than 100 drawings and watercolors. He was enchanted by the local landscape and light; his works from this period are rich in yellow, ultramarine and mauve. His paintings include harvests, wheat fields and general rural landmarks from the area, including *The Old Mill* (1888), a picturesque structure bordering the wheat fields.

Hospital in Arles (December 1888)

The exact sequence of events which led to Van Gogh's mutilation of his ear is not known.

After the altercation with Paul Gauguin, Van Gogh returned to his room, where he was assaulted by voices and severed his left ear with a razor, causing severe bleeding.

Van Gogh was found unconscious the next morning by a policeman and taken to hospital. Van Gogh had no recollection of the event, suggesting that he may have suffered an acute mental breakdown.

Saint Paul Asylum (1888-1889)

In the Saint Paul Asylum, the artist made a *tripartite nocturne series* of paintings consisting of *Café Terrace at Night* (September 1888), then *Starry Night Over the Rhône* later that same month and last *The Starry Night.*

The artist considered *The Starry Night* which one day would rank among his most famous works, to be a failure, according to what he wrote to his brother. *Starry Night* depicts a dreamy interpretation of the artist's asylum room's sweeping view of Saint-Rémy-de-Provence. It offers a rare nighttime glimpse into what the artist saw while in isolation (1).

Disease and affliction

Vincent Van Gogh suffered from several diseases, especially psychiatric conditions that influenced both his life and his works. He suffered from syphilis (1882) and during periods of acute mental pressure he had epileptic seizures (the artist was suffering from a disease unknown at that time, temporal lobe epilepsy) (2).

While in Paris, he began to suffer from minor paroxysms consisting of episodes of sudden terror, peculiar epigastric sensations, and lapses of consciousness. Observers reported occasions of an initial tonic spasm of the hand and a peculiar stare, followed by a confusional-amnestic phase. His use of absinthe, an alcoholic beverage with convulsant properties favored by French artists, appears to have played a crucial role in the precipitation of van Gogh's illness (3).

Shortly after leaving Paris, the painter wrote to his brother:

"I was surely about to suffer a stroke when I left Paris. It affected me quite a bit when I had stopped drinking and smoking so much, and as I began to think instead of knocking the thoughts from my head. Good heavens, what despair and how much fatigue I felt at that time"

He explains to his brother how he can resist periods of acute emotional stress, throwing himself in work altogether and consuming large amounts of alcohol: *"If the storm within gets too loud, I take a glass more to stun myself"* (4).

Because Van Gogh used lead-based paints there are some who believe he suffered from lead poisoning from nibbling at paint chips. It was also noted by Dr. Peyron that during his attacks Van Gogh tried to poison himself by swallowing paint or drinking kerosene. One of the symptoms of lead poisoning is swelling of the retinas which can cause one to see light in circles like halos around objects. This can be seen in paintings like *The Starry Night.*

Hypergraphia is a condition causing one to need to write continuously; this disorder is commonly linked to mania and epilepsy. Some believe that the massive collection of over 800 letters Van Gogh wrote during his lifetime could be attributed to this condition (5, 6)

The tumultuous life of the genius ended abruptly and too early. Vincent Van Gogh shot himself in a wheat field in Auvers, France but did not die until 2 days later at the age of 37 years old.

An analysis of van Gogh's illness and emotionality must not obscure the fact that the great artist also had great strengths. Apart from distinct episodes of madness when he used absinthe and had seizures, he maintained a remarkable degree of lucidity during his stormy life, as is well documented in his letters (7).

Dilemma

In his painting *Starry Night* (1889), Vincent van Gogh realizes a bizarre, central and specific structure. In the literature it is assumed that this structure is very similar to the neuroanatomic structure of the hippocampus (1, 8). But in his room, there is no sketch of the human hippocampus to inspire a possible connection with *Starry Night* painting.

In this paper, the authors try to show that this structure is just a brush motion, as there are no defining elements to prove that Vincent van Gogh had knowledge of neuroanatomy (figs. 3-5). The greater likelihood is that this element of the artist's painting resemblance more to an abstract graphical representation of a *Whirlpool Galaxy*, described and drawn first by Sir William Parsons, 3rd Earl of Rosse (1800-1867) in 1845 (fig. 6). This idea was, for the first time, brought to light by writer Michael Benson, in his 2014 book *Cosmigraphics* (9).

Davis, Philadelphia, Pa, USA, 5th edition, 1899, Edited by W. S. Hall assisted by P. L. Holland and E. P. Carlton) Epilepsy Research and Treatment Vol 2012, Article ID 176157

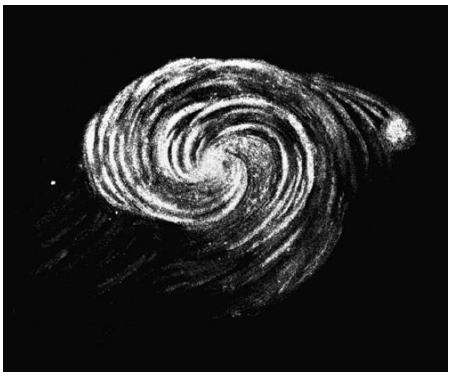

Fig. 6. Drawing of the *Whirlpool Galaxy* by William Parsons, 3rd Earl of Rosse in 1845, Cosmigraphics (2014) by Michael Benson

Starry Night is one of the most recognized pieces of art in the world. Honestly, it sometimes feels as if the painting's fame has exceeded that of its creator. It is a magnificent piece of art. That *Starry Night* resonates with so many people is a testament to how its beauty is timeless and universal.

CONCLUSIONS

The authors consider that the visual approach between the anatomical/radiological structure of the hippocampus and the formation painted by artist Vincent Van Gogh is just a coincidence. The artist did not have neuroanatomic knowledge and therefore could not paint his *morbus loci*, the structure is a simple brush motion.

An interesting approach to the interpretation of this structure is that it could represent a galaxy as it was designed a few years before *Starry Night* by Sir William Parsons.

Artistic works, either paintings, sculptures or literature, depend on a subjective view of the viewer/reader, the lover of "beauty", so it is difficult to formulate a clear opinion on the various elements of a creation.

ETIOLOGY AND ANTIMICROBIAL SUSCEPTIBILITY OF BACTERIAL PATHOGENS CAUSING URINARY TRACT INFECTION AT "SF. PARASCHEVA" INFECTIOUS DISEASES HOSPITAL (Abstract) **Aim:** Urinary tract infection (UTI) is one of the most common diagnosis in primary health care, which are treated with antibiotics. The diagnosis of UTI is suggested by clinical findings (dysuria, pollakiuria) and confirmed by microbiological examination of urine. The presence of pathogenic bacteria requires the immediate initiation of therapy in accordance with the results of the antibiogram. Management can be complicated by the increasing prevalence of antibiotic resistant strains. **Material and methods:** Microbial resistance and the etiology of bacterial pathogens was assessed among the UTI patients admitted to the "Sf. Parascheva" Infectious Diseases Hospital in Iasi, Romania. **Results:** The most frequent cause was gram-negative bacteria (GNB). Strains of *Enterococcus spp* and *Candida spp* have also been isolated. A percentage of 7.7% of the strains were beta-lactamase releasing. Regarding the antimicrobial susceptibility pattern of bacterial strains, we found increased GNB resistance to beta-lactam antibiotics. **Conclusions:** The results showed that *Escherichia coli* strains were the most frequently detected, followed by *Pseudomonas, Enterococcus, Enterobacter* species in a lower percentage. Treatment of UTI should be performed according to the results of the antibiogram, and for a sufficient period of time in order to prevent pandrug-resistant bacteria. **Keywords:** URINARY TRACT INFECTION, RESISTANCE, BACTERIAL PATHOGENS, BETA-LACTAMS.

Urinary tract infection (UTI) is an infection that affects part of the urinary tract and one of the most common bacterial infections acquired in the community and hospital settings. It is characterized by bacterial invasion and multiplication of infectious agents in the urinary tract, expressed as bacteriuria (1). Bacterial colonization in urine may be symptomatic or asymptomatic, bacteria invading the urinary tract by ascending or hematogenous (rare) routes (2).

In straightforward cases, a diagnosis may be made, and treatment given based on symptoms alone without further laboratory confirmation. In complicated or questionable cases, it may be useful to confirm the diagnosis via urinalysis or urine microscopy (3).

Urinalysis (preferably obtained from the same sample as the urine culture) may be suggestive of infection in the presence of leukocyturia (>20 PMN/mL of urine) and pathogenic organisms in urinary sediment (4). However, urinalysis can neither confirm nor exclude with certainty a diagnosis. Confirmation of UTI is obtained only by urine culture (5).

Additionally, in patients with recurrent infections other laboratory investigations, such as kidney and bladder X ray or urinary tract ultrasound are also indicated. Abdominal ultrasound can reveal anatomical anomalies of the urinary tract, urinary tract obstruction (stones, tumors) and can exclude hydronephrosis or presence of perinephric abscesses. Abdominal X ray may reveal the presence of radiopaque stones (6).

The bacteria that cause UTIs typically enter the bladder via the urethra. It is believed that the bacteria are usually transmitted to the urethra from the bowel, with females at greater risk due to their anatomy (7).

The reports of the European Centre for Disease Prevention and Control (ECDC) on the etiological spectrum of UTIs highlight a significantly increased percentage of *E. coli* strains, both in complicated and uncomplicated infections (6). Other incriminated strains were Klebsiella sp., Proteus, Enterococcus, Pseudomonas, Serratia and others, in much smaller percentages (5, 8).

The pathogens traditionally associated with UTI are changing many of their features, particularly because of antimicrobial resistance (9). The etiology of UTI is also affected by underlying host factors that complicate UTI, such as age, diabetes, spinal cord injury, or catheterization. Consequently, complicated UTI has a more diverse etiology than uncomplicated UTI (10), and organisms that rarely cause disease in healthy patients can cause significant disease in hosts with underlying anatomic, metabolic, or immunologic disease (11).

The treatment of UTI is established after obtaining the results of laboratory investigations, being individualized in accordance with the antibiogram result (12). There are cases in which the specific treatment should be completed with a supportive treatment, respectively with drugs that increase the antibiotic efficacy and reduce the risk of UTI recurrence (e.g. phytopharmaceuticals with cranberry extract containing proanthocyanins, a substance that inhibits adhesion of bacteria to the urinary tract epithelium and blocks their multiplication (13, 14).

MATERIAL AND METHODS

For the purpose of this study, from the hospital electronic database, we extracted all urine samples collected from patients with UTI between January 1st, 2018 and September 30th, 2018 from 1,015 patients hospitalized at the "St. Parascheva" Infectious Diseases Hospital, Iasi, Romania.

The inclusion criteria in the study included: children and adults (no age limit - range 7 month-93 years) and bacterial confirmation ($\geq 10^3$ UFC / mL). Therefore, were excluded from the study, people who presented sign and symptoms of ITU, but the bacteriological examination was negative.

We collected information on demographic data (age, gender, area of residence (urban or rural), disease symptoms, the presence of underlying disease or recurrences, causes of UTI, laboratory findings (urinalysis, urine culture) and antibiogram.

The informed consent of the patient was not necessary, given that the study was a retrospective one.

RESULTS AND DISCUSSION

During the 9 months interval, urine tests were performed in 1,015 patients who presented signs and symptoms of UTI (fever, dysuria, pollakiuria) (15), either at presentation, or during their hospital admission for other medical problem.

The clinical diagnosis of UTI is essentially based on medical history (includes an evaluation of urinary tract symptoms, history of UTI or other urinary tract problems, family history and sexual history). Urine tests (urinalysis - visual exam, microscopic exam, dipstick test) are the second important element in diagnostic testing. The gold standard for a urine test is to perform a bacteriological urine culture, with identification of the pathogen, with quantification and sensitivity testing (16). In our study, of the 1,015 tested patients 467 (46%) had positive urine cultures.

Of the 467 UTI patients included in the present study 332 (71%) were women, far more numerous than the males. Regarding the age group incidence, most patients were aged 51-to 70 years old (mean age 62 years old). This agrees with literature data that show, according to international statistics reported by ECDC, that during the reproductive years the presence of bacteria in the urine is 50 times more common in women, and that 50% of women will experience an episode of urinary infection during their lifetime (17).

Also, the same study indicates that approximately 75% of UTIs acquired during hospital stay are associated with a urinary catheter (18). In our study, these cases accounted for 13.5% (63) of the cases. Another cause of UTI found in our study was represented by nosocomial infections, which accounted for 167 (35.7%) cases.

In our study group, laboratory investigations revealed plurimicrobial flora (42 urine cultures revealed simultaneous infection with 2 different bacteria, 9 cultures with 3 bacteria). As to the causative pathogen, gram negative species were identified in 337 (72.1%) patients, *Enterococcus spp* in 105 (22.4%) patients. and *Candida spp* in 25 (5.5%) patients.

Statistically significant data were obtained for gram negative bacteria. The results showed that 195 (57.8%) of the isolates were *E. coli*, followed in descending order by *Klebsiella*, *Proteus* and *Enterobacter*. Compared with previous literature, these organisms had a lower frequency. Numerous studies show that *Escherichia coli* is the most common microorganism, followed by *Klebsiella* and *Proteus spp*, in order to cause urinary tract infections. And other studies show that the presence of Gram-positive bacteria, such as *Enterococcus* and *Staphylococcus*, has increased.

A number of 28 species of Enterobacteriaceae were beta-lactamase releasing (15 of *E. coli* and 13 of *K. pneumoniae*). Extended spectrum beta-lactamases (or ESBLs for short) are a type of enzyme or chemical produced by some bacteria. ESBL enzymes cause some antibiotics not to work for treating bacterial infections. Common antibiotics, such as cephalosporin and penicillin, are often used to treat bacterial infections. With ESBL infections, these antibiotics can become useless. The most common types of bacteria that produce ESBLs include *Escherichia coli* and *Klebsiella.* When these ESBLs bacteria cause infections that can no longer be treated by normal antibiotics the doctor will find another treatment to stop the new infection that's become resistant to antibiotics.

With regard to antibiotic resistance, we had chosen to study especially the resistance of the *E. coli* and *Klebsiella spp*

strains, which were found in a high percentage in the studied group.

Currently, studies have found high rates of resistance to classes of antimicrobial agents recommended for the treatment of UTIs by the United States and European guidelines.

This is the case of our study, where the analysis of antibiotic resistance of uropathogenic *E. coli* strains isolated from patients admitted to our infectious diseases hospital revealed that the highest resistance was found to Ampicillin (72.9%), followed by Fluoroquinolones (42.3%) and Cephalosporins (34.2%). Uropathogenic *E. coli* showed low resistance to Nitrofurantoin, Amikacin, and Gentamycin. For the *Klebsiella spp* strains isolated in this study, the highest resistance was reported to Fluoroquinolones (52.6%), followed by Ampicillin and Nitrofurantoin. In both cases no Colistin-resistance were recorded.

CONCLUSIONS

In most of our cases the etiology of UTIs was microbial, sometimes even plurimicrobial, in some cases co-infection with two or more bacteria being present. *Escherichia coli* remains the most commonly isolated uropathogenic, followed by *Klebsiella*, *Pseudomonas*, *Enterobacter*, *Proteus* and *Enterococcus* species. Urinary infections caused by Candida species were most likely influenced by the frequent and long-term use of antibiotics.

Because of the increased risk that antibiotic-resistant strains will develop and spread, new strategies for the treatment of UTIs are needed. Diagnostic algorithms can help to make the use of antibiotics more specific.

Treatment of UTIs should be initiated according to the antibiogram and continued for an adequate period of time in order to avoid pandrug resistance. The uropathogenic E. coli strains showed high resistance to beta-lactam antibiotics like broad-spectrum penicillin, while resistance of *Klebsiella* strains to fluoroquinolones has increased.

LIMITED INTERNAL COMBINED WITH EXTERNAL FIXATION OR SIMPLE EXTERNAL FIXATION IN TREATMENT OF OPEN TIBIAL DIAPHYSEAL FRACTURES ?

The conclusion of a recent article published in BMC Musculoskeletak Disorders is that the limited internal fixation combined with external fixation had good results compared with simple external fixation for managing open fractures. The researchers evaluated that additional internal implants did not significantly increase the risk of infection. In contrast, the combined fixation technique was beneficial for initial reduction and subsequent fixation stability, thereby permitting early rehabilitation and rapid healing with a low incidence of postoperative complications. More prospective comparative studies with larger samples and longer follow- up periods are required to accurately evaluate the clinical outcomes of this combined technique (Hao ZC, Xia Y, Xia DM, Zhang YT, Xu SG. Treatment of open tibial diaphyseal fractures by external fixation combined with limited internal fixation versus simple external fixation: a retrospective cohort study. *BMC Musculoskelet Disord*. 2019;20(1):311. Published 2019 Jul 3. doi:10.1186/s12891-019-2679-9).

EFECTELE ADMINISTRĂRII PREOPERATORII A PROSTAGLANDINEI E_1 ASUPRA FLUXULUI SANGUIN CEREBRAL LA NOU-NĂSCUTUL CU MALFORMAŢIE CONGENITALĂ CARDIACĂ DUCTO-DEPENDENTĂ

PROSTAGLANDIN E_1 PREOPERATOR ADMINISTRATION EFFECTS ON CEREBRAL BLOOD FLOW IN NEWBORNS WITH DUCTAL-DEPENDENT CONGENITAL HEART MALFORMATIONS (Abstract) : Although the absolute number of congenital structural heart disease has not changed over the years, more and more infants undergo surgical interventions in the neonatal period, increasing the number of children and adults with post surgical status of cardiac disorders. Prostaglandin E_1 (PGE_1) is the first line drug to maintain or reopen the ductus arteriosus, until surgical intervention can be made. Cerebral blood flow (CBF) is regulated by multiple factors, like pO_2, pCO_2, pH, cardiac output and systemic blood pressure. The aim of the study was to determine how CBF changes after PGE_1 administration in these newborns. **Materials and methods** : We studied the pO_2, pCO_2, mean systemic blood pressure, and cerebral blood flow velocities by colored and pulsed Doppler ultrasonography in 36 newborns with ductal dependent cardiac malformation before and after prostaglandin E1 administration, and correlated them to normal values for the age. **Results** : We found that cerebral blood flow velocities followed the variations of blood pressure in restricted pulmonary circulation ; improvement of oxygenation went parallel with decrease of cerebral diastolic velocities, and in aortic coarctation cerebral velocities decreased after introduction of PGE_1. **Conclusions** : PGE_1 administration improved cerebral blood flow velocities in all forms of cardiac malformations, due to reorganization of cardiac output and changes in oxemia. **Key words** : CEREBRAL BLOOD FLOW, PROSTAGLANDIN E_1, CONGENITAL HEART DEFECTS DUCTAL-DEPENDENT

RETROSPECTIVE STUDY ON THE ENDOSCOPIC THIRD VENTRICULOSTOMY

RETROSPECTIVE STUDY ON THE ENDOSCOPIC THIRD VENTRICULOSTOMY (Abstract): Hydrocephalus is an active distension of the ventricular system of the brain resulting from inadequate circulation of CSF. Hydrocephalus is the main pathology encountered in pediatric neurosurgery, making it by far the leading cause of brain surgery. **Materials and methods:** Although for a long-time shunt therapy (VPS) was the only therapy available for hydrocephalus, nowadays endoscopic third ventriculostomy (ETV) becomes a reasonable alternative method that seeks to reduce the risk associated with shunt malfunction and its lifetime dependence. The authors conducted a retrospective analysis of 157 children with hydrocephalus who were treated either ETV or VSP at Marie Curie Emergency Children's Hospital, Bucharest between 2016 and 2018.The purpose of this paper is to analyze the success rate of ETV, by counting the number patient who didn't need shunt placement within the 1 year after ETV surgery. **Results**: Among those 157 examined children, 46 underwent ETV and 111 underwent VSP as their first treatment. Among those from the first group, 18 patients were surgery-free after ETV while the others 28 needed shunt placement. We defined our success rate (39%) basing on the number of patients who didn't need any shunt placement within 1 year after ETV. We also reported a big tendency to failure for those within the ETV group who were already associated with intraventricular hemorrhage. **Conclusions**: In conclusion, according to our study ETV seems to be a reliable treatment for hydrocephalus children. Further investigations are necessary for understanding the reoperation probability in order to distinguish which treatment is long term beneficial. **Keywords:** VENTRICULOSTOMY, SHUNT PLACEMENT, SUCCESS RATE, PEDIATRICS.

Hydrocephalus is an active distension of the ventricular system of the brain resulting from inadequate passage of CSF leading to CSF accumulation. Hydrocephalus is encountered in 1-2 of every 1000 live births (1), this fact making it one of the main pa-

thology in pediatric neurosurgery. CSF is an ultrafiltrate of plasma, predominantly secreted (2) by the choroid plexus (70-80%), brain interstitial fluid, ependyma and capillaries, with a total volume of 10-60 mL in infants and 60-100 mL in children. Understanding the way this fluid circulates is an important step towards comprehending the pathology (3). Thus, from the choroid plexus which produce it, CSF circulates via the ventricular system to its point of absorption into the systemic circulation, leaving the subarachnoid space through arachnoid villi found along the superior sagittal venous sinus, intracranial venous sinuses, and around the roots of spinal nerves. Any obstruction or malformation encountered at the passage of CSF, cause an anormal accumulation of CSF and an increase in ICP, which further will lead to one or more of the following pathologic findings: atrophy of the white matter, chronic astrogliosis, neurons are selectively spared because of a more luxurious blood supply to the gray matter, spongy periventricular edema, fibrosis of the choroid plexuses, ventricular diverticula and thinning and elongation of the interhemispheric commissures.

Nowadays, the optimal treatment for pediatric hydrocephalus patients is still discussed since there exist several surgical approaches, yet their success rate was reported different according to each particular study (4).

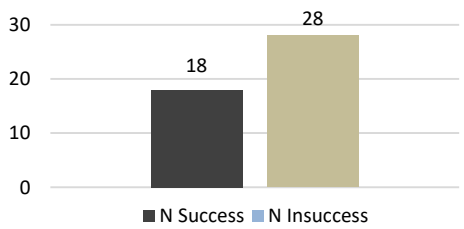

Fig. 1. Overall Success Rate

For a long time, shunt placement was the one leading approach in hydrocephalus. However, this procedure presents some disadvantages (5) such as decrease in life-quality, frequent obstructions, infections (due to an immature immune system, skin integrity and low nutrition in the first months of life). Also, even low-pressure valves could lead in time to over drainage (slit ventricles, subdural effusions and secondary craniostenosis) requiring conversion to a higher-pressure valve and anti-gravitational mechanism. Inflammation and hemorrhage (5) can complicate the shunt insertion and leads to isolated symptomatic ventricles (ataxia, cranial paresis, vital signs alteration) or multiloculated hydrocephalus.

As many significant advances have recently been made in Endoscopic Third Ventriculostomy (ETV), more and more surgeons chose this path of treatment for its benefits such as low shunt rate dependence and minimally invasive approach. According to previous literature, success rate SR of ETV depends on several important variables such as etiology, age, experience of the surgeon. For example, higher ETV SR was reported by several studies including aqueduct stenosis patients, and lower SR was observed in postinfectious and posthemoragic cases (6), facts that were also encountered and confirmed by what we present in this article.

In our study, we included our single-center experience in ETV treatment for hydrocephalus in children. Success rate was analyzed by dividing our group of patients in subgroups and a short review of literature was presented at the end.

MATERIALS AND METHODS

This is a retrospective study done be-

tween 2016 to 2018, at "Marie Curie" Emergency Children's Hospital, Bucharest, including at the beginning 157 patients who were examined for hydrocephalus. Data were collected from the medical charts and other relevant Imagistics (CT and MRI). In order to be included in the study patients had to have one of the following aspect of the pathology: triventricular hydrocephalus with lateral and third ventricles dilated, aqueduct stenosis, arachnoid cyst, history of hemorrhage or infection as a principal cause of hydrocephalus. Exclusion criteria were: multiloculated hydrocephalus or other complex cases which required multiple interventions in the past, cases with prior CSF diversion history. After establishing these criteria, those (111) who didn't meet them were excluded from the study. In the end, our study included 46 patients (28 males : 18 females) who were addressed to ETV as their first treatment for hydrocephalus. The mean age of the patients was 1 year and 8 months, ranging from neonates to 17 years old children. Out of the 46 patients, 15 were born premature, with a low birth weight and a mean birth age of 33.4 months (27 months being the minimum). From those who were born premature, 11 out of 15 were admitted for hydrocephalus due to hemorrhage or infection. The average Cranium Perimeter CP at hospitalization was 44 cm.

We analyzed several variables such as: etiology, age at the operation, birth-age, interval between operations in case of failure. Our distribution of patients according to their etiologies are showed in first table, which includes the number of cases for each pathology, the frequency of the pathology in our study and in the literature. Compared to the literature, our center reported a higher frequency of post hemorrhagic (28% to 3-13%%) and postinfectious (19% to 3-6%) cases and a lower frequency of tumors (8% to 29-47%). Based on anatomical and developmental considerations, we divided our patients in 3 groups, respectively: < 6 months Group with 30 patients, 6 months - 2 years Group with 6 patients and > 2 years Group with 6 patients to analyze the impact that age has on SR.

We defined our success rate SR basing on the number of patients who didn't need any other intervention at one-year follow-up. Diagnosis of hydrocephalus was made based on some important clinical aspects such CP growth, tight anterior fontanelle (7) and on the basis of imagistics which revealed one of the following: "Mickey Mouse" ventricles, ascending or thinning of *corpum callosum*, obstruction of the foramina Magendi and Luschka, periventricular edema.

Failure of ETV was considered when patients presented one of the following pathological aspects even after the operation: increase intracranial pressure, increase occipital-frontal circumference, bulging of the anterior fontanelle or any other symptoms of intracranial hypertension. Eventually, these patients needed to be treated by shunt placement VPS or re-ETV. About the procedure, ETV is performed with head flexed so that the burr hole site is at the highest point (8).

The optimal trajectory is achieved with a burr hole, placed just anterior to the coronal suture and slightly medial to the mid-pupillary line.

After penetrating into the lateral ventricle, foramen Monroe could be identified at the confluence of thalami-striate vein with septal vein and caudate vein. Passing through foramen Monroe, the endoscope enters into the third ventricle. ETV is per-

formed into the triangle formed between the 2 mammillary bodies and infundibulum where the floor of third ventricle is bulged, right anterior to the tip of basilar artery. Anterior to the infundibulum can be seen the optic tract and posterior to it can be seen the clivus. Penetrations into the prepontine cistern should be done carefully to avoid the injury of the basilar artery. In some cases, it would be necessary to perforate also the membrane of Liliequist, found beneath the floor of the third ventricle. The fenestrations usually around 4-5 mm, it is furtherer enlarged with a Fogarty balloon. This last step is usually done with little bleeding.

TABLE I
Distribution according to their pathologies

Types of cases	N	Frequency in our study (%)	Frequency in literature (%) (9, 10, 11, 12, 13)
Posthemoragic	13	28%	3-13%
Postmeningitis	9	19%	3-6%
Intraventricular Cyst	7	15%	5-6%
Aqueductal Stenosis	5	10%	15-31%
Tumors	4	8%	29-47%
Myelomeningocele	4	8%	3-6%
Others (Syndromes, Aneurysms)	2+2	4% + 4%	6-22%

RESULTS

In our study included a total of 46 patients diagnosed with hydrocephalus, reporting an overall SR of 39%. In the rest of the patients re-ETV or VPS was performed.

We analyzed patients according to their etiology and data set was labeled in the second table.

TABLE II
ETV SR according to each pathology

Type of Case	N	Number of Success	Success Rate
Post-hemorrhagic	13	1	7%
Post-meningitis	9	1	11%
Intraventricular Cyst	7	6	85%
Aqueduct Stenosis	5	5	100%
Tumors	4	3	75%
Myelomeningocele	4	0	0%
Genetic Syndromes	2	1	50%
Vascular Cases	2	1	50%
TOTAL	**46**	**18**	**7-100%**

The greatest SRs were 100%, 85% and 75% in the patients with aqueduct stenosis (5/5), intraventricular cyst (6/7), respectively with tectal tumors (3/4). Our lowest SRs were reported in post-hemorrhagic (13 patients) and post-infectious patients (9 patients), respectively 7% (one patient) and 11% (one patient). In patients with myelomeningocele (n=4) our SR was 0/4. We also reported syndrome-cases: Dandy Walker (1) with no SR and NF-1 (1), with SR=100%. Regarding vascular cases, we reported patients with Galen Aneurysms malformations (2 patients) with the final SR of 50%. In patients who were successfully treated, clinical symptoms were solved - the PC decreased, and anterior fontanelle lowered in tension. We reported the mean PC of 44 cm, ranging from 38 cm to 49 cm at discharge, which according to CDC Growth Charts corresponds at the 50th percentile with the age of 6 months which was the exact mean age of our successful cases. Regarding age distribution our data was collected and presented in table III.

TABLE III
Relation between age, etiology and SR

Etiology of hydrocephalus	Premature	< 6 months	6-24 months	> 24 months
Posthemoragic	5	0/12	1/1 (100%)	-
Postmeningitis	6	1/7 (14%)	0/1	0/1
Intraventricular Cyst	-	2/3 (66.7%)	2/2 (100%)	2/2 (100%)
Aqueductal Stenosis	2	2/2 (100%)	2/2 (100%)	1/1 (100%)
Tumors	-	1/1 (100%)	0/1	2/2 (100%)
Myelomeningocele	2	0/3	-	0/1
Genetic Syndromes	-	-	0/1	1/1 (100%)
Vascular Cases	-	0/1	1/1 (100%)	-
TOTAL	**15**	**6/30 (20%)**	**6/8 (75%)**	**6/8 (75%)**

We experienced 20%, 75% and 75% SR in < 6 months Group, in 6 months - 2 years Group, respectively in > 2 years Group. According to this table, SR increases with the age, being the lowest in neonates, and the highest in children above 2 years. In those who were born premature, we reported SR of 26% (4 out of 15). The mean interval between operation in case of failure was 51 days with minimum of the days for neonates and a maximum of 192 days (6 months) in 6-24 months Group. Those cases in which re-ETV was used, even though presented an initial favorable prognostic, yet they ended up with VPS. Because of the associated risks, these situations were encountered in almost all of our post-hemorrhagic and post-infectious patients (18) who were classified as unsuccess. No mortality was reported in the study.

DISCUSSION

VPS was for a long-time the standard permanent option, however this technique presents many late complications such as

infections, obstruction or over drainage with formation of slit ventricles. Nowadays, with the development of in neurosurgery, ETV seems to be the method of choice in many aspects of children hydrocephalus.

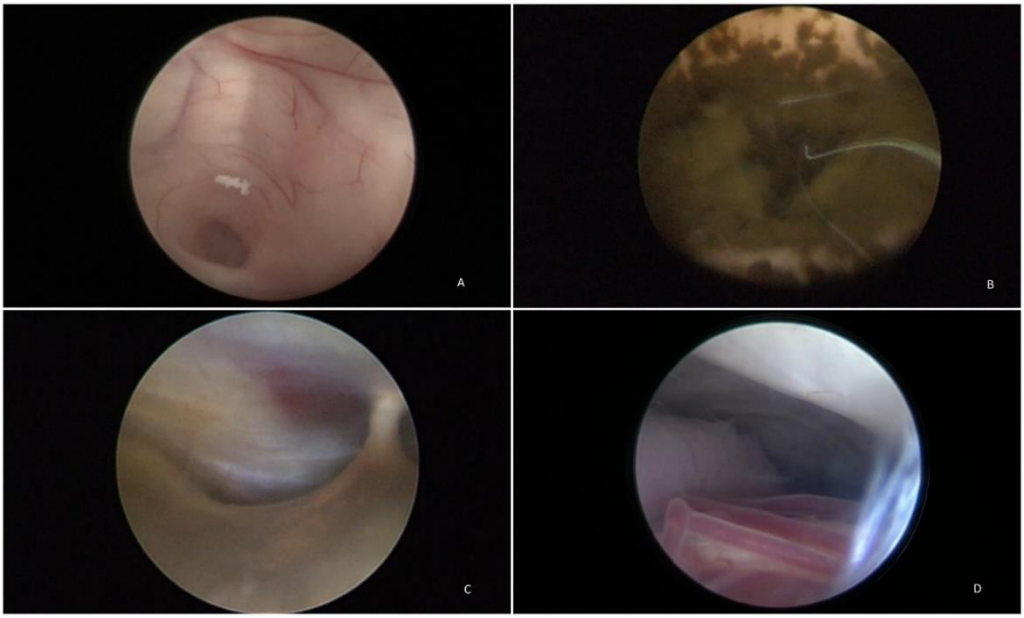

Fig. 2. Normal and pathological aspect of Sylvius Aqueduct (A, B).
Scarring of the pre-pontine Cistern (C).
Normal aspect of the pre-pontine cistern with Basilar Artery and Pre-pontine arteries (D).

In our study, we reported 46 patients with various types of hydrocephalus, from different ages, yet predominant infants < 6 months (tab. III). We defined our SR as the number of patients who didn't need within 1-year after ETV. Over time in literature there was a big controversy about whether or not it is good to use ETV in patients < 1 year (14, 16). Several authors (8, 11, 15, 16) reported very good outcomes ranging between 60-70%, while others reported poor outcomes with SR between 20-35%. In our study, in the < 6 months Group, we reported 100% SR for aqueduct stenosis (2 cases, < 6 months Group) and tumors cases (1 case, < 6 months Group), with good outcomes, SR=66.70% in intraventricular cyst cases (2 cases < 6 months Group) and poor outcomes in post-meningitis (1/7, SR of 14%) and post-hemorrhagic or other vascular cases (0), with a final overall SR of 20%. We agree that ETV is a reliable treatment that should be use for hydrocephalus in this age group, yet not only age but also etiology is an important prognostic factor for the postoperative outcome. In the other 2 groups (6 months - 2 years, and > 2 years), we reported 8 age-etiology subgroup in which SR was 100%. This again sustain the strong correlation between age, etiology and SR.

According to literature (16), age is an

important factor in the postoperative evolution of hydrocephalus children. Many studies reported a lower SR in infants < 6 months than in the rest of the patients. Bognar *et al.* (17) reported a SR of 36% in patients < 6 months, and a SR of 73% in patients > 1 year, while Kulkarni et al reported a SR of 44% and 69% in < 6 months, respectively in > 6 months Group.

The primary explanation of this ETV failure in infants might be explained by CSF poor absorption (18). After being produced by the choroid plexuses CSF circulates through the ventricular system and finally leaves the subarachnoid space through arachnoid villi found along the superior sagittal venous sinus (3 to 5 mmHg pressure gradient between the subarachnoid space and venous sinus), intracranial venous sinuses, and around the roots of spinal nerves. However, in infants these arachnoid granulations are poorly developed, increasing the risk of accumulation of CSF into the brain. Moreover, because the skull sutures are not closed very well, ICP cannot get high enough to help CSF be absorbed. Last but not the least, ETV failure in infants < 6 months could be correlated with a high tendency to develop new arachnoid membranes, usually on both sides of the basal artery between the clivus and pons, but not only. Regarding this last point, we reported at least 6 cases of multiloculated hydrocephalus, that were not included in this study due to the exclusion criteria, with severe complications which needed multiple endoscopic interventions and shunt revision till the equilibrium was achieved. In these situations, it is important to acknowledge that the surgeons usually face a distorted anatomy which is accompanied by many deposits of hemosiderin (fig. 2.B) due to blood degradation, without the normal landmarks as in figures 2.A, 2.D. From our experience one of the prognostics factors for an ETV failure is the scarring of the pre-pontine cisterns (fig. 2.C), which happened in almost all of the 6 cases mentioned above. In this situations success is barely obtained and the primary goal would be rather to lower the intracavitary pressure, reduce the number of catheters and number of revisions. From our experience, myelomeningocele surgeries (4) were unsuccessful. One possible explanation is that 3 out of 4 cases were patients < 3 months and may have suffered from infant CSF flow problems.

CONCLUSIONS

In conclusion, our study analyzed several factors such as: etiology, age at the operation, birth-age, interval between operations in case of failure, being an observational report describing whether or not this factors influence the success rate. According to our study ETV seems to be a reliable treatment for hydrocephalus children (16). Successful rate of ETV depends on age, being lower in infants under 6 months, and higher in children above 2 years, but also depends on each etiology being higher in aqueduct stenosis, tumors, intraventricular cysts patients, and lower in post-hemorrhagic and post-infectious patients. Our conclusions are still preliminary, and we believe that further investigations with a larger sample of patients will be necessary in order to report more statistically relevant data.

RETROGRADE SEMIRIGID URETEROSCOPY *VERSUS* EXTRACORPOREAL SHOCK WAVE LITHOTRIPSY IN THE TREATMENT OF URETERAL CALCULI BETWEEN 5-15 mm (Abstract): Ureteral calculi below 15 mm are treated either by retrograde semirigid ureteroscopy or extracorporeal shock wave lithotripsy (ESWL). Controversy regarding the best method still exists, and authors favor one or another procedure. The aim of this retrospective study was to compare these two procedures. **Material and methods:** The study compared the results of 71 patients treated by retrograde ureteroscopy and 57 patients treated by extracorporeal shock wave lithotripsy. **Results:** Out of the 71 patients treated by ureteroscopy, 60 (84.5%) were stone-free, one month after the procedure. In 11 cases (15.5%), the stone could not have been reached or the fragments migrated in the pyelocaliceal system (residual fragments). Out of the 57 patients treated by ESWL, 21 (36.9%) required only one session to break the stone, 33 (57.9%) needed two sessions, one patient, three sessions and in two cases, the stone could not be focalized. The stone-free rate was evaluated three months after the last session, and it was 87.7% for ESWL. There was only one complication in each group. **Conclusions:** The difference of stone-free rate between the two procedures was not statistically significant. Ureteroscopy achieved the status stone-free earlier, in contrast with ESWL, who needed a longer time. Both procedures had lower rate of complications. **Keywords:** RETROGRADE URETEROSCOPY, ESWL, STONE-FREE RATE.

Retrograde ureteroscopy and extracorporeal shock wave lithotripsy (ESWL) are both, utilized methods in the treatment of ureteral lithiasis, for stones under 15 mm in the long diameter, according with EAU Guidelines (1). Some studies shows a better outcome for ureteroscopy (2, 3, 4). Other studies demonstrate a higher stone-free rate for ESWL (5, 6, 7), while different authors observed a similar, good rates of success (8, 9). There are also controversies regarding the preoperative stenting, as some authors demonstrated that the use of ureteral stents lower the stone-free rate after ESWL (10, 11), while others considered that there were no differences (9). Due to these con-

flicting results, some urologists tend to indicate as the first line of treatment ureteroscopy, while others indicate ESWL, according to their experience. We have conducted a study in which we compared the stone-free rates of the two procedures, the time to achieve that goal and the rate of complications.

MATERIAL AND METHODS

We have enrolled in the study 71 consecutive patients with ureteral stones with the size between 5-15 mm, which were operated by ureteroscopy between January and April 2018 in the Urological Clinic of "Dr. C.I. Parhon" Hospital Iasi with a *Olympus* Ureteroscope and 57 consecutive patients with the same diagnosis, who were treated by ESWL in the "Elytis" Hospital Iasi with a *Siemens Lithostar* unit, between August 2017 and December 2018. The diagnoses were based on echography, Plain radiological films (KUB), and in many cases, urography, when the diagnoses were in doubt. Control for the remaining fragments or stones after the two procedures were made in the same mater as for diagnosis. The status stone free was evaluated at one month for ureteroscopy group, because these patients came back for the extraction of the double JJ stents, routinely placed after the procedure, at 2-4 weeks after the procedure. The patients was considered stone free, if there were no radiopaque images on the KUB X-ray and no stones or pyelocaliceal distention on the ultrasound examination. The same control procedure was applied for searching residual fragments in the ESWL group, but the control was made at 3-4 weeks and at three month after the procedure. We waited three month even when the stone was fragmented, due to the long time needed for fragments to pass spontaneously. So, the stone free rate was compared at one month for ureteroscopy group, and at three month for ESWL group. We named residual fragments, all stones over 3 mm. The decision for the specific procedure was made by the patients on the basis of an informed consent form. We have enrolled in the study all these patients with ureteral stones, with or without previous inserted ureteral JJ stents, with a BMI under 35. The exclusions criteria were patients with lost follow up, with stones over 15 mm, or multiple ureteral lithiasis. We have compared the stone free rates between the two groups, at one and three months and the rate of complications.

Statistical analysis. Data were presented as means with standard deviation or numbers and percentages frequency, as appropriate. Between-group comparison was performed using the Chi-square test or Fisher's exact test for categorial variables and the independent t test for the remaining variables. We considered a 2-sided $p<0.05$ to be significant. All statistical analysis were performed using the *SPSS for Windows, version 19.0.1* (SPSS Inc, Chicago, Illinois).

RESULTS

There were 128 patients included in the study. The mean age of the patients was 51,5 years. A total of 61(47,7%) were males. The most stone location was the lumbar region (52.3%) and the majority of patients, 81 (63.3%) required only 1 session of ESWL or ureteroscopy. 65 patients (50.8%) had the stone under 10 mm, 74 patients (57.8%) had previous inserted JJ stents and 59 patients (46%) had the stone on the left side. Only 34 patients (26.6%) were with ureterohydronephrosis, all other were without obstruction, or with JJ stents (tab. I).

TABLE I

Characteristics of the two groups

		ESWL		Ureteroscopy		
		N	%	N	%	p value
Mean age		45.7±12.4		56.0±15.2		<0.001
Number of patients	Men	31	54.4	30	42.3	0,17
	Women	26	45.6	41	57.7	
Localization of the stone	Lumbar	31	54.4	36	50	0.81
	Iliac	3	5.3	14	20	0,03
	Pelvic	23	40.3	21	30	0.37
Size of the stone	5-10 mm	30	52.6	35	49	0,71
	11-15 mm	27	47.4	36	51	
With obstruction (ureterohydronephrosis)		20	35	14	19.7	0.13
Without obstruction		14	24.6	6	8.5	0.03
With preoperatory JJ stents		23	40.4	51	71.8	<0.001
With obstruction and JJ stents		43	75.4	65	91.5	
Right ureteral stone		34	59.6	35	49.3	0.52
Left ureteral stone		23	40.4	36	50.7	

Patients that had performed ureteroscopy were older, had a higher incidence of iliac stone location, were more likely to have a previous JJ stent insertion and required more frequently only 1 session than patients that had performed ESWL. In ESWL group, patients had more frequent obstruction. All other characteristics of the two groups were similar, without statistically significant differences. The difference characteristic between the two groups does not influence the outcome of the procedures, so they are not a bias factor (tab. II).

TABLE II

Results of the procedures

	ESWL		Ureteroscopy		
Number sessions	N	%	N	%	p value
1	21	36.9	60	84.5	<0.001
2	33	57.9	5	7	<0.001
3	1	1.7	-	-	-
Unsuccessful procedure cannot focalized the stone	2	3.5	-	-	-
	5	8.8 with residual fragments	11 cannot reach the stone or fragments migrated in pyelocaliceal system	15.5	0.65
Stone free	50	87.7	60	84.5	0.88

Out of the patients with residual fragments in the ureteroscopy group, 9 (12.7%) had the stone in lumbar position, 1 (1.4%) was iliac and 1 (1.4%) was in pelvic region. Out of the 5 patients with residual fragments in the ESWL group, 4 had JJ stent inserted.

As complications, in ureteroscopy group, 1 (1.4%) post operatory fever, over 38 degrees Celsius was recorded and was cured with intravenous antibiotics, while in the ESWL group, 1 (1.8%) subcapsular hematoma, did not require drainage and was in resolution three months after the procedure.

DISCUSSION

Our study has some major particularities. Many patients in the ESWL group (40.4%) had previously inserted JJ stents, which is known to affect the success of the procedure (10, 11), so, it was expected to see a lower proportion of stone-free patients. On the contrary, a very good success rate was noticed, higher than in other studies (3, 12, 13), probably due to the fact that we performed two or even three sessions to break the stones and we applied a relative high energy level, according to manufacturer's specifications. This good result came with a higher risk of renal injury in lumbar stones, and the reason for some studies to report a higher complications rate after ESWL (14). Because many patients had JJ stents, we did not report any case who required post ESWL stenting as in other studies (15), having the advantage of a very low risk of obstruction. Many studies (3, 16) report a low success rate after one session of ESWL as in our study, because, without JJ stent, the risk of obstruction and renal impairment is high and it is not expected to wait, to perform another session. So, preprocedural JJ stent insertion has disadvantages but also advantages, allowing multiple sessions, until reaching the goal of stone-free. We evaluated the proportion of patient cured, without residual fragments, at three month, and not at one month and this fact can also explain the higher stone-free rate after ESWL.

Another particularity is that in the ureteroscopy tents, previously placed for infected ureterohydronephrosis, or recurrent renal colic. The ureteroscopy was performed weeks after the placement of the JJ stent and it was expected to see a higher rate of success, as in other studies (2, 4, 6, 17) of over 95%. Our lower rate can be explained by the fact that after weeks of stenting, the ureteral mucosa is inflamed, and can create difficulties in advancing and reaching the stone. The ureteroscopy is performed routinely after maximum 2 weeks after the placement of the JJ stent, in centers with a smaller waiting list for the patients. Compared with other studies, our complication rate was much lower as in other studies (16-20), similar to the ESWL group ($p<0.001$) (3).The major drawback for successful ureteroscopy, was the location in the lumbar region, and even with the previously inserted JJ stents, there were 9 patients (12.7%) in whom the stone couldn't be reached or with fragments migrated in the pyelocaliceal system.

When we compare the two procedures, we see that the stone-free rate is similar ($p<0.001$), but for the ESWL group the status stone-free is achieved later. The rate of complications is very low in both groups, these methods are safe, and the results are better than those mentioned in the European guidelines (1) with a higher potential of complications for ureteroscopy. In our experience, the risk of complications

does not constitute a reason for the patients to refuse the ureteroscopy. In our study, the patients have chosen the ESWL, because of the potential risk of anesthetic complications during ureteroscopy or for personal reasons.

CONCLUSIONS

In our study, retrograde semirigid ureteroscopy and ESWL are both effective to achieve the goal of the procedures, the stone-free status, with comparable results, even when JJ stent is placed preoperatively. Ureteroscopy cure the patients quicker, with a similar rate of complications as ESWL. However, for stones in lumbar ureter, the success rate drop sharply, so ESWL is recommended as the first line of treatment. When available, flexible ureteroscopy and not semirigid ureteroscopy can be recommended if the patients accept the anesthetic risk. Finally, in our opinion, the option for a procedure or another should be the patient's choice, after a thorough counseling.

NEWS

DEVELOPMENT OF EFFECTIVE VACCINES FOR ENTEROTOXIGENIC *ESCHERICHIA COLI*

Diarrhea in children is caused mostly by enterotoxigenic *Escherichia coli* (ETEC). Vaccination could be an effective way to prevent ETEC diarrhea. A specific vaccine was not developed yet due to ETEC strains heterogeneity. In The Lancet Infectious Diseases, Firdausi Qadri and colleagues examined the safety and immunogenicity of enterotoxigenic *E. coli* vaccine (ETVAX). ETVAX is an oral, inactivated, vaccine which contains four E. *coli* strains that overexpress adhesins CFA/I, CS3, CS5, and CS6, mixed with a recombinant protein, LCTBA. It previously shown to be safe and highly immunogenic in Swedish and Bangladeshi adults. The study was based on a randomized phase 1/2 trial in children and infants. They showed that ETVAX was safe and well tolerated by children. At a quarter of an adult dose, adverse events like mild vomiting or fever were rare. They observed that the immunogenicity of ETVAX was age-dependent: children aged 12–59 months had significant increases in IgA antibodies in lymphocyte secretions (ALS) targeting all five vaccine antigens, but children aged 6-11 months had significant ALS and fecal IgA responses to only three antigens (CFA/I, CS3, and LTB). The accomplishment of ETVAX in ETEC-endemic regions it's shaded by some concerns like the multitude of ETEC adhesins that are not targeted in the vaccine, or the immunity to the B subunits of heat-labile toxin, but not to the toxic heat-labile A subunit, nor to the heat-stable enterotoxin (Qadri F, Akhtar M, Bhuiyan T, et al. Safety and immunogenicity of the oral, inactivated, enterotoxigenic Escherichia coli vaccine ETVAX in Bangladeshi children and infants: a double-blind, randomized, placebo-controlled phase 1/2 trial. *Lancet Infect Dis* 2019; https://doi.org/10.1016/ S1473-3099(19)30571-7).

PREDICTIVE FACTORS OF THE OUTCOME OF SURGICAL PROCEDURES FOR ENTERAL FEEDING IN PATIENTS WITH MALIGNANT *VS.* NONMALIGNANT DISEASES

PREDICTIVE FACTORS OF THE OUTCOME OF SURGICAL PROCEDURES FOR ENTERAL FEEDING IN PATIENTS WITH MALIGNANT *VS.* NONMALIGNANT DISEASES (Abstract): Surgical feeding procedures are required as a treatment for malnutrition that occurs in a wide range of malignant or benign, digestive or extradigestive diseases. Choosing the best approach in each case is important for achieving a correct nutritional support. **Aim**: To identify the predictive factors of the efficacy of the different surgical feeding procedures, comparatively in benign *vs.* malignant pathology. **Material and methods**: Retrospective, cross-sectional, observational study of a group of 276 cases with various benign and malignant diseases. Correlations were established between the initial disease, type of surgical techniques for enteral feeding and the postoperative outcomes. Statistical analysis was performed using the Chi-square test for dichotomous variables and the Mann-Whitney and Kruskal-Wallis tests for ordinal and continuous variables. **Results:** Most patients with either benign or malignant digestive diseases underwent Gavriliu's high gastrostomy with peritoneal cuff (73.6%; 91% respectively), performed under local anesthesia. The patients with benign extradigestive diseases and 35% of the patients with malignant extradigestive diseases underwent percutaneous endoscopic gastrostomy (PEG), but monitoring was short, 30 days, respectively. In early postoperative follow-up, PEG is associated with faster recovery and lower gastric stasis volume. Classic gastrostomy is still an option in cases with severe strictures due to esophageal or head and neck malignancies. The main long-term prognostic factor is the possibility of ensuring the correct number of calories and volume of food. **Conclusions:** The efficiency of feeding techniques is long-lasting, largely uninfluenced by the underlying disease. The acquisition of the nursing elements would makes it possible to maintain these surgical feeding solutions both in the hospital setting, but especially in the outpatient setting. **Keywords**: GASTROSTOMY, TUBE FEEDING, PERCUTANEOUS ENDOSCOPIC GASTROSTOMY, MALIGNANCY, PREDICTIVE FACTORS.

Surgical feeding procedures are required as a treatment for malnutrition that occurs in a wide range of malignant or benign, digestive or extradigestive diseases. Impossibility of normal feeding has extremely serious consequences on the

metabolism of carbohydrates, lipids, and proteins, as well as on the immune system. Malnutrition in cancer patients can limit their response to treatment, surgery, chemotherapy, and radiation therapy (1). A loss of over 10% in body weight at diagnosis is a poor prognostic factor for survival (2, 3). An adequate calorie intake and the restoration of a normal body mass index (BMI) are essential before a curative intervention, both for malignant and nonmalignant upper digestive stenosis.

Numerous conditions may compromise the passage of food along the digestive tract, even when permeable, such as severe head injury, brain tumors, cranioencephalic trauma, cerebral hemorrhage and cerebral infarction, because of gag reflex impairment or dysfunction. In these critically ill patients, enteral nutrition support plays an important role, many studies demonstrating the positive effect of enteral feeding vs parenteral feeding in preventing septic complications in ICU patients (4-7).

There is a wide variety of surgical feeding procedures described in the specialized literature, using the classical open, laparoscopic, or endoscopic approach, but there is relatively little data on the clinical parameters with predictive value of their maintenance and long-term efficacy.

AIM

To identify the predictive factors of the efficacy of the different surgical feeding procedures, comparatively in benign *versus* malignant diseases.

MATERIAL AND METHODS

Retrospective, cross-sectional, observational study of a group of 276 cases admitted over a 10-year interval, with various benign and malignant diseases characterized by the long-term impossibility of physiological nutrition, which is an indication for enteral nutrition. The studied parameters were gastric stasis volume at 24, 48, 72 hours, calorie intake, gastric capacity at 1, 3, 6 and 12 months, peristomal erythema, body mass index (BMI), corroborated with the sequential assessment of biological parameters over different follow-up intervals. Correlations were established between the initial disease, type of surgical feeding procedure, and postoperative outcomes. Statistical analysis was performed using the Chi-square test for dichotomous variables and the Mann-Whitney and Kruskal-Wallis tests for ordinal and continuous variables.

RESULTS

Most patients (56.52%) had a malignant digestive disease, followed by benign esophageal stenosis (21.73%), and extradigestive neoplasia (17.39%). In 12 cases (4.34%) the surgical feeding procedure was performed for benign extradigestive disorders (neurological diseases, patients hospitalized for a long time in ICU).

In the study group, men aged 41 to 60 years were most susceptible to benign digestive diseases as compared to women whose percentage was much lower and attributed to a much younger age (18-40 years). Males are at a much higher risk of developing both digestive and extradigestive diseases than females; the odds of the disease being malignant, whether digestive or extradigestive, is also higher in males (χ^2=8.508, p = 0.004) (tab. I).

Of the total study cases, 22.82% were admitted to hospital as emergencies for febrile syndrome, severe cachexia or dysphagia with odynophagia. Preoperative clinical parameters were particularly relevant

for malignant digestive disease. Thus, of the patients diagnosed with digestive malignancies 57.1% had fever, 56.5% dysphagia, 62.8% odynophagia, 55% abnormal BMI, 66.7% sialorrhea, 57.7% cough, 52.6% low hemoglobin levels, 45.1% leukocytosis, 61.9% nitrogen retention, and 58% coexistence of radiological lung opacities (tab. II).

Lung opacities (Rx)	23.2	**58.0**	3.6	15.2

Choosing the surgical procedure for enteral feeding was significantly influenced by the diseases type: most patients with either benign or malignant digestive diseases underwent Dan Gavriliu's high gastrostomy with peritoneal cuff (73.6% and 91%, respectively), performed under local anesthesia. The patients with benign extradigestive diseases underwent surgery by endoscopic approach, but monitoring was short, 30 days, respectively. A significant percentage (approx. 35%) of patients with malignant extradigestive diseases underwent percutaneous endoscopic gastrostomy, but the monitoring was also short, 30 days, respectively.

The patients were followed-up at 24, 48, and 72 hours, 7 days, 3, 6, 9 and 12 months postoperatively. The followed descriptive postoperative parameters were coded as 0 = absent and 1 = present and were analyzed using *IBM SPSS Statistics version 20.0* to find the most relevant parameters in terms of clinical variation and disease course (tab. III).

Statistical analysis showed that showed statistically significant variation during the first 7 days of postoperative monitoring were: fever and gastric liquid volume and appearance. The variation of these parameters was not influenced by the benign or malignant nature of the underlying disease, but by the surgical technique used.

During the first 24 hours, the most relevant parameters for monitoring the postoperative course were: gastric stasis volume (small or medium), biliary stasis (0.889) and fever (0.707). The clear appearance of gastric stasis has no significance, being within the normal postoperative variability (tab. IV).

Malignant extradigestive diseases	64.6	0	0	0	35.4	0	48
Total	216	5	14	21	19	1	276

TABLE IV
Variance of the postoperative clinical parameters

Descriptive Statistics				
	Minimum	Maximum	Mean	Std. Deviation
Fever	0	1	.11	.312
BP	0	1	.03	.161
Surgical wound	0	1	.01	.085
Pain	0	1	.01	.085
Incontinence of gastrostomy	**0**	**0**	**.00**	**.000**
Peristomal erythema < 2 cm	0	1	.01	.118
Peristomal erythema > 5 cm	**0**	**0**	**.00**	**.000**
Gastric stasis 0-50 mL	0	1	.56	.496
Gastric stasis 50-100 mL	0	1	.36	.481
Gastric stasis 100-150 mL	0	1	.08	.266
Serosanguineous gastric stasis liquid	0	1	.03	.168
Biliary stasis liquid	0	1	.26	.441
Clear stasis liquid	0	1	.71	.455

During the postoperative 24 hours - 7 days interval, the statistically significant parameters recommended to be monitored are of gastric stasis appearance [(normal, clear gastric stasis (R2 = 0.951), biliary stasis (R2 = 0.942)] and gastric stasis volume (R2 = 0.703). The incidence of fever (R2 = 0.272) is a parameter considered unimportant during this postoperative interval. Therefore, during the postoperative 1-7 days interval, the clinical course of the patient carrying a feeding tube for enteral nutrition can be best monitored by monitoring gastric stasis volume and appearance.

Kruskal Wallis test was used to verify whether the 6 surgical procedures for enteral feeding used in the study group led to different performances of the postoperatively monitored parameters. The most obvious differences generated by the surgical feeding technique are at the level of biliary/gastric stasis. To explore these differences, the Mann-Whitney test was applied, comparing the surgical procedures two by two. The means of the ranks indicate favorable results when using the classic Dan Gavriliu's gastrostomy technique compared to gastrostomy - jejunostomy with respect to avoiding fever, low BP values, and ensuring the best possible outcome for the surgical wound (sig.=0.000).

The probability of gastric stasis with bilious appearance is higher with the classic Gavriliu's gastrostomy technique than with PEG (sig. =0.018). This can be attributed to gastric paresis associated to surgical trauma, which is more significant in the classic vs endoscopic approach. However, there are limitations of the study generated by the different number of cases analyzed for each surgical technique used.

As to long-term follow-up, between 1 and 12 months, the statistical significance of the monitoring parameters depended both on the type of feeding procedure and the disease that required the surgery. Elements such as: good stoma continence, clear, small gastric liquid volume (0-50 mL), and peristomal erythema < 2 cm are indicators of favorable outcome, associated with the possibility of managing a high calorie intake and higher volumes of food

administered per day, in both benign and malignant groups, with improvement of BMI and metabolic imbalances. On the contrary, the signs that suggest sepsis, such as fever, malignancy, pulmonary and mediastinal X-ray lesions, nitrogen retention, and low BMI are risk factors for complications such as stoma incontinence, large erythema, with the impossibility of administering the minimum number of daily calories. The statistical analysis was carried out to identify those parameters that influence the presence of feeding stoma incontinence, stasis volumes greater than 100 mL, large skin erythema > 5 cm, and tolerated feeding volume. The analysis of statistical data showed statistically significant differences between the minimum tolerated volume and the number of calories administered in benign vs malignant diseases (sig. = 0). In the study group, statistically significant correlations were recorded only for the malignant digestive disorders treated by palliative Dan Gavriliu's gastrostomy.

At 1-month follow-up, in these patients normal hemoglobin levels proved to be a significant predictor of volume of stasis < 50 mL, suggesting a favorable course (probability 81.1%, sig. < 0.05). At the 3-month follow-up, the absence of radiological pulmonary abnormalities was a significant predictor (sig. = 0.004) for the presence of peristomal erythema < 2 cm, a factor of favorable outcome (prediction value 64.7%). Statistical analysis also showed a strong correlation between continence and volume of gastric stasis < 50 mL (prediction value 95.7%).

At the 6-month follow-up, statistical analysis showed that the presence of peristomal erythema < 2 cm in the group of patients with malignant digestive diseases who underwent Gavriliu's gastrostomy was correlated with: tolerated volume per administration, number of meals, volume administered per day (sig. = 0.001), and overall the possibility of administering the necessary daily calories (p = 0.037). The impossibility of administering the necessary calories is also a significant predictor of Rx pulmonary damage 6 months after surgery in this group (sig. = 0.004). The negative saturation coefficient B = -.032 from Step 2, Logistic Regression actually indicates that patients with malignant digestive disorders, who are given more calories are less likely to develop lung parenchymal damage (the probability of prediction is 97.3%).

DISCUSSION

The surgical procedures for enteral feeding are becoming increasingly important by expanding their use in a medical conditions whose complexity and diversity require effective long-term calorie support. In order to ensure the hydroelectrolitic necessities, it is important to consider the fluid losses through fistulas, diarrhea, perspiration, urine, based on which the qualitative and quantitative supply will be calculated (8). The amount of fluids to be administered per 24 hours is estimated, on average, at 2,000-2,500 mL, to which NaCl, KCl, calcium, magnesium and other electrolytes are added, depending on the data provided by the blood and urine ionogram. The nutritional requirement is calculated considering the basal energy requirement and the additional energy consumption related to patient's suffering and initial nutritional status. The caloric requirement is about 25 kcal/kg body weight multiplied by a correction factor called stress index. The assessment of nutritional status is taking into account clinical criteria (such as

BMI, arm circumference, subcutaneous adipose fold) and biological criteria (total protein, albuminemia, prealbumin or transthyretin (TTR) with normal values of 310 ± 35 mg/L, transferrin 2.8 ± 0.3 g/L, retinol binding protein (RBP) with normal values of 62 ± 7 mg/L. These objective parameters can be used to assess malnutrition and to identify an improvement in nutrition after surgery (9, 10).

The literature on the prospective outcome factors of enteral tube feeding surgery is relatively limited. Surgical feeding techniques are numerous, but details on the long-term effectiveness of the methods or nursing challenges are not given. This study is assessing the predictive factors of the outcome of surgical procedures for enteral feeding. It was confirmed that the identification and monitoring of these parameters are important from stage I until the abolition of feeding stoma, the major goal being to maintain the necessary caloric values administered.

Most of the study patients underwent Dan Gavriliu's gastrostomy with peritoneal cuff, which aims, as major principles of continence, at creating an efficient gastric volume and maintaining the local morpho functional integrity). This procedure remains an effective surgical technique in the modern era, being characterized by a wide addressability (it can be practiced in any surgical department with minimal instruments and even under local anesthesia), indicated in patients with severe esophageal stenosis in different stages of therapy (8). Another benefit is the possibility of passing blended real food through G-tube, providing the necessary number of daily calories at affordable cost in low income patients requiring long-term enteral feeding. Quick recovery and easy nursing principles comply with the international efforts made to produce and sustain a change in medical practice in the direction of reducing hospitalization costs, with the concomitant development home-care health assistance, recuperative and palliative medicine services (11).

The main drawback of this technique is early postoperative gastric stasis, which is significantly increased compared to the minimal invasive approach.

PEG can be an excellent minimally invasive option in cases with a permeable digestive tract (12, 13), but there are limitations that need to be considered such as the costs and availability of the PEG kit and pre-hydrolyzed nutrient solutions, as well as the coexistence of a upper GI endoscopy service. Clinical studies revealed a low risk of respiratory complications in the case of neoplastic patients wearing both tracheostomy and gastrostomy, probably due to the smaller diameter of the tube. The clinical studies demonstrated that in patients diagnosed with inoperable head and neck who need tracheostomy it is recommended to perform a PEG while the digestive tract is still permeable and place a "stand-by" G-tube before the progression to dysphagia with a progressive degradation of the nutritional balance and cachexia (14-19). On the long-term follow-up of patients who underwent PEG, there may be limitations regarding the maximum daily calorie intake due to the osmotic effect and secondary induced diarrhea associated with high volumes of feeding solutions (20), but further studies are needed due to relatively short follow-up in this group.

Surgical gastrostomy is alternative when an endoscopic approach is not feasible. Post pyloric nutrition is indicated in patients with gastric feeding intolerance

and may be achieved through PEG with jejunal extension, percutaneous endoscopic jejunostomy, and surgical jejunostomy (10, 21, 22).

CONCLUSIONS

The classic and endoscopic percutaneous surgical feeding procedures complement each other, technical support and skills being important to perform both categories of techniques, select the technique carefully for the appropriate indication. After analyzing a significant number of surgical feeding procedure, we conclude that their integrity and long-term outcome were not influenced by the type of disease that required them. In early postoperative follow-up, the main difference between classical and minimally invasive surgical techniques was the reduced volume of gastric stasis after PEG and PEG-J, possibly influenced by their minimally invasive nature, the duration and type of anesthesia with reduced postoperative paresis, and non-digestive diseases for which these techniques were used (predominantly neurological). Recovery after PEG is faster than after surgical gastrostomy, but still, there are indications for a surgical gastrostomy: severe esophageal strictures, advanced head and neck malignancies, technical failure of PEG, or unavailability of the facility or funds to perform PEG or of the specific nutrient solutions. Even though surgical gastrostomy and jejunostomy are simple procedures, they should be done meticulously to achieve good results and avoid complications as these patients are already nutritionally compromised. The main long-term prognostic factor is the possibility of ensuring the correct number of calories and amount of food. The acquisition of nursing elements would make it possible to maintain these surgical feeding solutions both in the hospital setting, but especially in the outpatient setting.

SALVAGE OF THE LIMB WITH CRITICAL SIZE BONE DEFECT USING FREE VASCULARIZED FIBULA (Abstract): The critical bone defect is not yet well defined, but it is well known that the free vascularized fibula (FLAP) transfer represents the gold standard in the reconstruction of complex bone defects associated with other soft parts defects, both post-traumatic and belonging to other etiologies. **Material and methods**: We will be presenting a lot consisting of three male patients, that in regard to the wounds caused by an accident with industrial machines involved, were diagnosed with forearm-localized type III C Gustilo-Anderson open fractures, and residually displayed radius defects across a length of 10-12 centimeters, which required us to opt for free vascularized fibula transfer with cutaneous island, in all three cases. **Results:** The results were good in all cases. Within one single case the cutaneous island displayed a discreet venous congestion which demanded the use of leeches, and eventually turning out very well. **Conclusions:** The treatment of the critical bone defects required ample, microsurgical interventions performed in multidisciplinary teams, the autologous bone remaining the best option for bone reconstruction, being the best growth factor and bone stimuli source, with no immunological modifications or risk of disease transmission. **Keywords :** LIMB, CRITICAL BONE DEFECT, FLAP.

The management of post-traumatic bone defects and vicious consolidations and post excision for tumor pathology or other etiologic factors, represent a challenge within the everyday life orthopedic practice (1). The absence of a standardized definition of critical bone defects is frequently referenced in literature and determines conflicts of opinion regarding their management (2-4). A widely accepted definition in literature describes critical bone defects as being bigger than 2 centimeters and takes more than 50 percent of the long bones' circumference, but this theory is controversial when it comes to the anatomical region and the state of the soft tissue in the vicinity of the defect (3).

The relative rarity of this type of pathology leads to the lack of an evidence and some management guides. Therapeutic attitude in regard to bone defects requires a multidisciplinary understanding of the pathology, as well as considering the fac-

tors concerning the patient age, the existence of other chronic conditions, the nutritional status, smoking, the status of the neighboring tissues, the local vascularization and the severity and extension of the wound) and the factors that have to do with the surgeon's experience (1). The election treatment for critical bone defects remains the autologous bone transfer, due to the safety that it offers when it comes to the transmission of illnesses and the immunological response, as well as the fact that it is the most available source of growth factors and bone stimuli (5). It is the technique that conglomerates osteogenetic, osteoinductive and osteoconductive effects, which is the main reason why it is still regarded as the gold-standard method in the treatment of critical bone defects treatment (6). We will be presenting a series of three post-traumatic bone defects involving radius which demanded the free vascularized fibula transfer with cutaneous island.

MATERIAL AND THE METHODS

We have studied a series of three male patients with ages between 46 and 59 years. They were all the victims of some accidents caused by industrial instruments, displaying open, forearm-localized type III C Gustillo-Anderson fracture. In two of the cases, the left thoracic limb was involved and only in one of the cases, the right thoracic limb was, all of the three patients being right-handed. All three patients underwent surgery in the plastic surgery and reconstructive microsurgery clinic in Iasi, after the informed consent on their behalf had been obtained. The three patients residually displayed, after the emergency performed surgical intervention, radius-localized bone defects of between 8-10centimetres in size, placed in the superior third of the forearm (fig. 1).

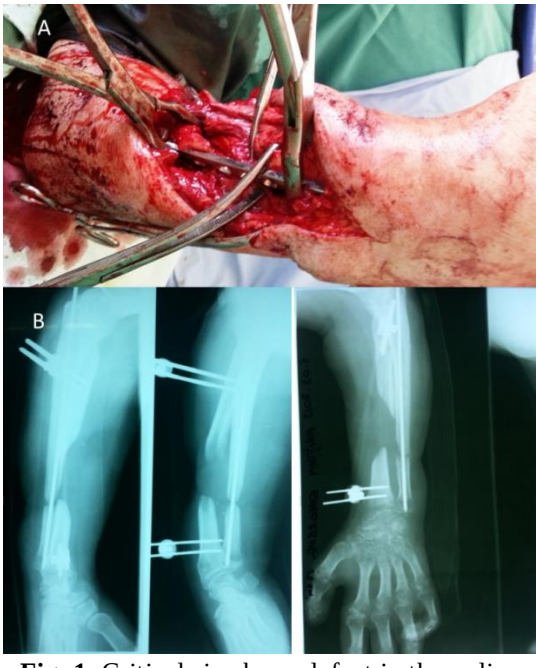

Fig. 1. Critical size bone defect in the radius
A. intraoperative image; B. radiological aspect

After the thorough analysis of the clinical parameters, associated pathologies and the vascular status of the donor, receptor areas and the radiologic examination performed in order to precisely estimate the bone defect.

In all of the cases, there were registered massive muscular losses in regard to the soft tissue parts, the initial wounds using cut by crushing mechanism. In all of the cases, a pre-surgery sketch was made after a Doppler exam, by marking the receptor vessel, the one included in the flap, the cutaneous island the bone segment that eventually required collection. In all of the cases the receptor area was around the pelvic floor, localized on the same side as the traumatized thoracic one (fig. 2).

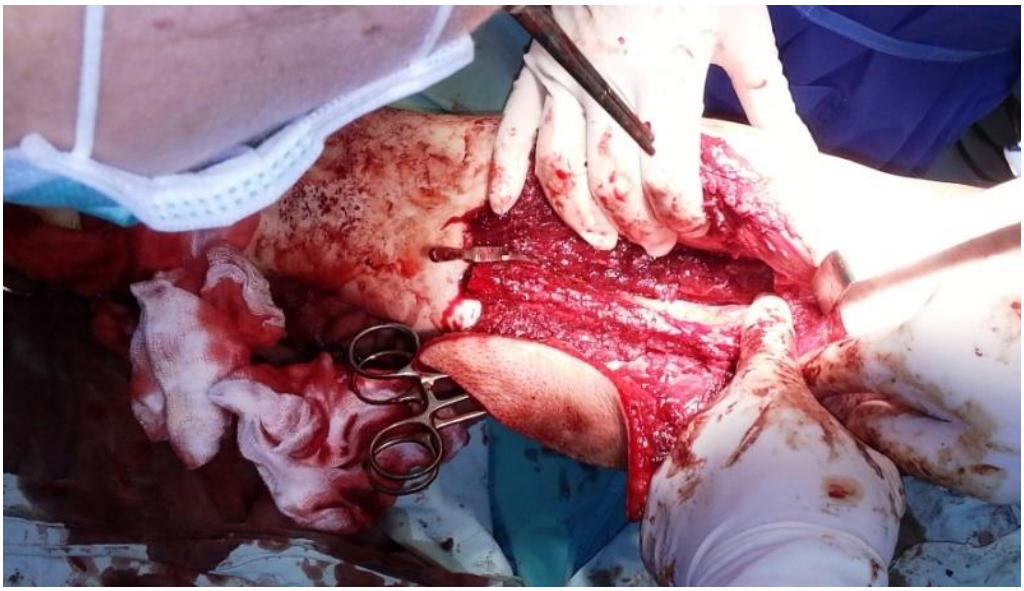

Fig. 2. Donor site

he surgical intervention took place under general anesthesia with oro-tracheal intubation. The osteosynthesis was done through the internal fixation stabilized with a plate and nails, these offering the advantage of an active mobilization with an important role in active and complete recovery (fig. 3, fig. 4).

The microsurgical intervention time went smoothly in all cases, with no incidents or accidents during the surgery. The microsurgical anastomosis was made between the peroneal artery of the flap and radial artery in all of the three cases. Two venous anastomosis were performed at each transfer. The post-surgical care was on average, 10 days. In all cases the flap included both the bone segment and the cutaneous island with sizes between 6 and 10 centimeters which was necessary for the coverage of the bone and the monitoring of the flap's viability. The closure of the donor zone was performed using a drainage. The average period of time in which the bone consolidation was obtained, radiologically objectified, was 5 months.

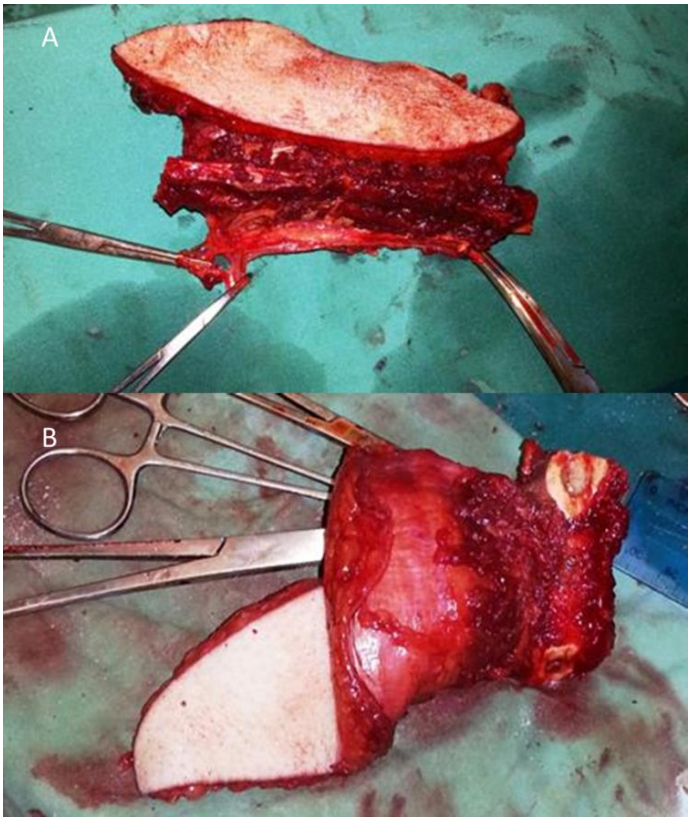

Fig. 3. A. Osteofasciocutaneous flap harvested from fibula and B. ready to be anastomosed at the recipient site

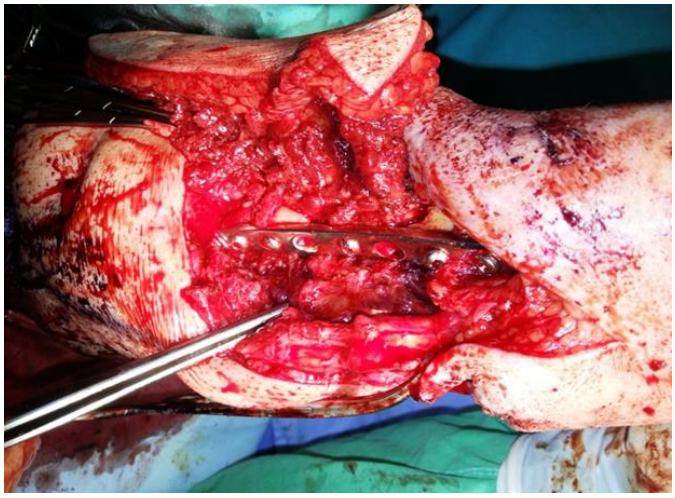

Fig. 4. Osteofasciocutaneous flap in place, after osteosynthesis with plate and screws and microsurgical arterial and venous anastomosis

RESULTS

In all three cases the post-surgical evolution was good. However, in the case of the oldest patient a slight venous congestion could be noticed, which was eventually treated by applying biological leeches for 3 days.

The cutaneous integration was qualitative 14 days after the surgical intervention.

The bone integration's assessment started 3 months after the surgery with a final evaluation expanding to 3 years (fig. 5).

Fig. 5. Radiological aspect A. Immediate postoperatively; B. At 3 years follow-up

In all cases the outcomes were very satisfactory. There were no registered immediate or distant complications and only in one case there was identified a venous congestion that was treated using biological leeches for 3 days (fig. 6).

Fig. 6. Clinical aspect at 3 years postoperatively. Morbidity on the donor area's level was minimum.

DISCUSSION

The indications concerning the reconstruction of a limb expanded throughout the last decades, which helped with avoiding amputation in a lot of cases. Vascularized bone transfer could be performed only after the 1960's, when Jacobson and Suarez perfected microvascular anastomosis techniques and the microsurgical instruments (7). In 1975, was performed the first free bone transfer for the reconstruction of a tibia defect. Since then and until now, it remains the workhorse flap for the reconstruction of limb-localized critical bone defects (8). FVFF passed the time stage and further enjoys success due to the several advantages that it incorporates (9). Because the fibula is a straight, tubular bone with a high density of the cortical and is sectionally triangle-shaped, it is regarded as ideal for the reconstruction of critical bone defects on the limbs (10, 11). Adults can have this bone harvested as a straight bone segment with a length of 26 centimeters. The fibula, having a diameter similar to the one of the radius and the ulnar bone and can easily enter the medullar channel of the tibia, femur and humerus (12, 13). Even though it benefitted from technological progress throughout the time, FVFF is still a complicated technique that requires a long surgery time that may increase the rate of possible complications and comorbidities when it comes to the donating areas, simultaneously introducing the idea of a lengthy anesthesia use, thus the indications concerning FVFF are extremely important and must be considered at all costs.

Critical post-traumatic bone defects are frequently associated with complex lesions of the soft tissues presenting reconstruction difficulties. Due to these reasons the use of the fibula as a composite osteo-fascio-cutaneous flap offers advantages to the concealing of a long and straight bone defect. At the same time, the reconstruction of a soft tissue defect of dimensions between 24/10 centimeters, through a unitary flap, anastomosed at only one vascular pedicle. The cutaneous island of the composite flap has an extremely important role in the post-surgery monitoring of the flap's viability (14). Among the FVFF indications there are included: segmentary loss of bones larger than 6-8 centimeters after tumor resection, traumatic bone loss, osteomyelitis, or the lack of the fracture's consolidation because of the infection (15, 16).

In the included cases of this study FVFF was used as a method of reconstruction of bone defects with sizes between 8 and 10 centimeters (17, 18). FVFF can be also suggested for smaller defects where the biological healing had failed, or a high risk of failure exists. The free vascularized fibular transfer can be considered as a therapeutic solution in the case of avascular bone necrosis, the loss of the bone and the soft tissues that require complex reconstructions and the young patients that require the conservation of the growing cartilage (19). There are cases in which the great defects of the soft tissues cannot be treated by using other techniques (20).

All patients included in this study were males, as well as more exposed to environments with higher risk of being traumatized (21, 22).

The estimated success rate in specialized literature varies between 76 and 100 percent (23, 24). The use of hirudotherapy for the treatment of venous congestion is frequently referenced in literature (25). The free transfer of vascularized fibula is an ample surgical intervention during which there can appear complications when it comes to the donor site. Complications when it comes to

the donor site can appear both during the free transfer of vascularized fibula and the anastomosis to the level of the receptor area and at the moment of bone fixation. The osteosynthesis mode and the consolidation time in the reported case are similar to the ones reported in literature.

CONCLUSIONS

The free transfer of vascularized fibula is commonly used for the reconstruction of critical size bone defects and leads to good results. Although technically, it is a complex intervention, it is preferred because the bone integration is qualitative and fast, the autologous bone remaining the best option for bone reconstruction, being the best source of growth factors and bone stimuli, with no immunological modifications or risk of disease transmission.

NEWS

CANNABINDIOL LOADED MICROPARTICLE – A POTENTIAL DRUG TO IMPROVE BREAST CANCER HEMOTHERAPY

Breast cancer chemotherapy treatment toxicity is still a challenge for clinicians because, even if the cancer is treated, the quality of life is reduced due to the persistence of adverse reactions caused by anticancer drugs. A study recently published in *International Journal of Pharmaceutics* demonstrates the antiproliferative effect of Cannabidiol (CBD) as loaded microparticles on tumor cells models in vivo and *in ovo*. The study shows that CBD microparticles are efficient as monotherapy, and also in co-administration with Paclitaxel (PTX) and Doxorubin (DOX) relieving extended antiproliferative activity. The co-administration of CBD and PTX or DOX showed a synergistic effect, with the possibility to lower the doses for anticancer drugs, and so to decrease toxicity of these drugs and, in the same time, to improve the overall anticancer effect. On the other hand, it's proved that CBD is efficient in treating the nausea and pain, as side effects of chemotherapy, so the benefit is double. In conclusion, this study provides, for the first time, evidences of the potential use of CBD-loaded microparticles in combination with paclitaxel or doxorubicin in the treatment of breast cancer. (Fraguas-Sánchez AI, Fernández-Carballido A, Simancas-Herbada R, *et al*. CBD loaded microparticles as a potential formulation to improve paclitaxel and doxorubicin-based chemotherapy in breast cancer. *Int J Pharm* 2020; 574: 118916).

WHAT GOES WRONG IN SURGICAL PATIENTS WITH CONCOMITANT *CLOSTRIDIUM DIFFICILE* INFECTION DISEASE? RISK FACTORS FOR IN-HOSPITAL MORTALITY (Abstract) **Aim:** to evaluate the possible anthropometric, clinical, biological, and pathological factors that could be associated with an increased mortality of the surgical patients with concomitant CD infection. **Material and methods:** The study was carried out on a group of 123 surgical patients who were operated in the IIIrd Surgical Unit of the "Sf. Spiridon" University Hospital Romania and were diagnosed with CDI during hospitalization. **Results:** We noted 20 deaths among the patients from our study group. Characteristic for the deceased patient's group was the presence of sepsis before or after CDI diagnosis ($p = 0.001$). The involving of a parenchymal organ ($p = 0.001$) and the presence of metastases ($p = 0.025$) were significantly higher in the deceased patient's group. Reintervention induced an estimated risk of death approximately 2-fold higher ($p = 0.002$). The estimated risk of death was slightly higher in patients with renal chronic disease ($p = 0.001$), obesity ($p = 0.009$), Diabetes Mellitus ($p = 0.005$) and chronic cardiac insufficiency ($p = 0.05$). All patients who died had surgical diseases requiring postoperative antibiotic treatment ($p = 0.001$) especially with Cephalosporin ($p = 0.003$) and Clindamycin ($p = 0.047$). The use of proton pump inhibitor and anticoagulant medication was statistically higher in patients who died. **Conclusions:** Unfavorable evolution of surgical patients with CDI is highly associated with obesity, renal chronic disease, chronic cardiac insufficiency, diabetes, chronic oral anticoagulants prior to CDI, treatment with third generation cephalosporin, clindamycin, and PPI after surgery. **Keywords:** *CLOSTRIDIUM DIFFICILE* INFECTION, SURGICAL PATIENTS, MORTALITY IN SURGICAL PATIENTS WITH CD INFECTION.

Clostridium difficile infection (CDI) is the most frequent nosocomial infection. Infection of the colon with the *Gram-positive* bacterium *Clostridium difficile* is potentially life threatening, especially in elderly people and in patients who have dysbiosis of the gut microbiota following antimicrobial drug exposure (1). There are some medical conditions, treatments and other factors that have already been demonstrated to increase the risk for CDI. Most important of those are sex, age, antibiotic treatment, and proton pump inhibitor (PPI) use, preexistent inflammatory bowel disease, healthcare facility contact and

obesity (2-7).

The aim of the study was to analyze the in-hospital mortality of the surgical patients diagnosed with CDI. We also aimed to evaluate the possible anthropometric, clinical, biological and pathological factors that could be associated with an increased mortality of the surgical patients with concomitant CD infection.

MATERIAL AND METHODS

We studied the files of all consecutive surgical patients who were operated in the IIIrd Surgical Unit of the "Sf. Spiridon" University Hospital Iasi, Romania, between 2015 and 2019 and were diagnosed with CDI during hospitalization. Data were retrospectively collected, and we included in our study emergency and elective surgical cases, with oncologic and nononcologic diseases. The inclusion criteria were surgical patients of more than 18 years old who developed postoperatively CDI. Patients with relapsed CDI were excluded from our study cohort. Our study group was We noted the general data, such as sex, age, blood type and provenience of the patient. The main surgical diagnosis, the type of the disease (oncologic, emergency), the associated diseases and postoperative complications were also noted. Regarding the surgical treatment of the patients, accordingly to the main disease, we evaluated the type of intervention in terms of the affected organ (parenchymal or hollow viscus), the type of operation (emergency or elective surgery), the need of mechanic bowel preparation before surgery, antibioprophylaxis, prophylaxis of CDI, the using of any other medication, the treatment of CDI and the length of stay before and after diagnosis of CDI. The infection with *Clostridium difficile* was documented by EIA (enzyme immunoassay) testing of toxin A and B from the stools. The studied group was divided into two subgroups, consisting in patients who survived and patients who died. *Statistical analysis*. Categorical variables were reported as percentages, and differences between groups were statistically assessed using *ANOVA* and *Fisher's exact test.* Statistical analyses were performed using *SPSS 11.0* (SPSS Inc., Chicago, IL, USA) and $p < 0.05$ was considered statistically significant.

RESULTS

143 patients with surgical interventions and postoperative developed CDI were initially included in the study. Of those, 20 patients presented one or multiple relapsing infections, so they were excluded. In the end, 123 patients were eligible, of whom we noted 20 deaths. None of the patients in our study developed toxic megacolon and surgical intervention as treatment for CDI was not indicated in any patient, as all the patients in our study had mild-moderate forms of CDI.

The group of patients who developed CDI postoperatively and died had a slightly higher average age compared to the survivors (67.55 *vs.* 65.61 y; $p = 0.526$). They were predominantly male (65% *vs.* 54.4%; $p = 0.464$) and had urban origin (60% *vs.* 58.3%; $p = 0.545$) (tab. I).

Characteristic for the deceased patient's group was the infection with both types of toxin (A and B) (100% *vs.* 76.9%; $p = 0.016$) and the presence of sepsis before or after CDI diagnosis (45% *vs.* 0%; $p = 0.001$). Referring to the main surgical disease, the involving of a parenchymal organ (45% *vs.* 9.7%; $p = 0.001$) and the presence of metastases (10% *vs.* 0%; $p = 0.025$) were significantly higher in the deceased patient's group (tab. I).

When evaluating thy type of surgical procedure, the highest estimated risk of death was associated with the performance of an enterectomy (RR = 5.15; IC95: 0.34-78.9; p = 0.736) and necrosectomy (RR = 5.15; IC95: 0.77-34.5; p = 0.424), but the result cannot be extrapolated to the general population. Reintervention induced an estimated risk of death approximately 2-fold higher (RR = 1.93; IC95: 1.00-3.69; p = 0.002) (tab. II).

When we evaluated the risk of mortality in relation with comorbidities, the statistical analysis showed that the estimated risk of death was slightly higher in patients with renal chronic disease (RR = 1.91; IC95: 1.06-3.45; p = 0.001), obesity (RR = 1.39; IC95: 1.0-1.91; p = 0.009), Diabetes Mellitus (RR = 1.33; IC95: 1.04–1.69; p = 0.005) and chronic cardiac insufficiency (RR = 1.18; IC95: 1.05–1.37; p = 0.05) (tab. III).

TABLE II

Relation between type of surgical procedure and mortality in patients with concomitant surgical disease and *Clostridium difficile* infection

Surgical intervention	Death (n=20)		Survivor (n=103)		Fisher's Exact Test	RR	CI 95%

Biochemical parameters showing the presence of inflammatory syndrome had significantly higher mean values in deceased patients in comparison with the survivors (p = 0.001). The mean value of White blood cells, C Reactive Protein (CRP) and platelets lymphocyte ratio were higher in the deceased patient's group (tab. IV).

Among the deceased patients, 90% received preoperative antibioprophylaxis treatment (90% *vs.* 51.5%; p = 0.001). All patients who died had surgical diseases requiring postoperative antibiotic treatment, but prior to CDI diagnosis (100% *vs.* 65%; p = 0.001) especially with Cephalosporins (60% *vs.* 25.2%; p = 0.003) and Clindamycin (10% *vs.* 1%; p = 0.047). The use of proton pump inhibitor and anticoagulant medication was statistically higher in patients who died. Also, all deceased patients received CDI prophylaxis and CDI treatment (tab. V).

DISCUSSION

Risk factors for CDI may be divided into three general categories: host factors (immune status, comorbidities), exposure to *Clostridium difficile* spores (hospitalizations, community sources, long-term care facilities), and factors that disrupt normal colonic microbiome (antibiotics, other medications, surgery) (7). As in our study all the patients had postoperatively developed CDI infection, we tried to find the differences between the characteristics of deceased patients and of the survivors by referring not only to the underlying diseases, types of surgery and treatment but also to the factors related to the CDI infections, meaning the risk factors and the treatment of it.

Regarding the use of antibiotics, although nearly all antibiotics have been associated with CDI, clindamycin, third generation cephalosporins and fluoroquinolones have traditionally been considered to pose the greatest risk (8, 9). Our study shows that in the deceased patient's group, the use of third generation cephalosporins and clindamycin was higher than in the survivor's group. We mention that all patients received specific treatment for CDI in accordance with the guidelines (10).

Exposure to gastric acid-suppressive medications, such as histamine-2 blockers and PPI, may be a potential risk factor for development of CDI, therefore there are studies that conclude that given that PPI are overprescribed in surgical settings, consideration should be given to stop PPI, when they are not necessary, especially in patients at high risk of CDI (11, 12). In our study, the proportion of use of the PPI was higher in the deceased patients. Another type of treatment we referred to in our study is the chronic anticoagulant treatment prior to CDI, whose percentage is higher (p=0.001) in the group of deceased patients. Up to date, we found no data in literature showing that chronic oral anticoagulants is somehow related to CDI. We consider that our statistical result shows a higher incidence of comorbidities requiring

chronic anticoagulant treatment in surgical patients who developed CDI for whom the evolution was unfavorable.

We also assessed the type of surgical disease, procedure and type of organ affected by the main disease for which the patient was hospitalized. In terms of type of intervention, we found no differences between the rate of emergency procedures *vs.* elective procedures in the two groups formed by the deceased patients and the survivors. More, the rate of death was not associated with a specific type of intervention or organ approached by surgery. Only the rate of reinterventions was statistically higher in the group of deceased patients (p=0.002). The presence of sepsis nonrelated to CDI, metastases and the parenchymatous organ (liver or pancreas) as the site of the primary surgical site of the surgical disease were associated with a higher mortality.

It has been already demonstrated that there are some types of surgical procedures that are more likely to increase the risk of CDI, such as colectomy, small-bowel resection, gastric resection and lower extremity amputation (13, 14), but there have never been demonstrated a relation between a specific type of surgical intervention and higher mortality in surgical patients developing postoperative CDI. Assessing the comorbidities of the patients, as expected, diabetes, obesity, renal chronic disease and chronic cardiac insufficiency were associated with unfavorable evolution of the patients. It is already known that diarrhea in CDI may be accompanied by mild abdominal pain and cramps and if prolonged, it may result in altered electrolyte balance and dehydration. When this occurs in patients with severe comorbidity, particularly after surgery, non-severe CDI may increase morbidity significantly (15).

CONCLUSIONS

Death of the patients with *Clostridium difficile* infection occurring postoperatively is associated with the presence of sepsis, metastases and reinterventions. Unfavorable evolution of surgical patients with CDI is highly associated with obesity, renal chronic disease, chronic cardiac insufficiency, and diabetes. Patients requiring chronic oral anticoagulants prior to CDI and patients requiring treatment with third generation cephalosporins, clindamycin and PPI after surgery are associated with a higher mortality rate.

CONFLICT OF INTERESTS AND FUNDING

The authors declare that there is no conflict of interest and they received no specific funding regarding this scientific research.

NEWS

ACUTE PANCREATITIS DURING COVID-19

Abdominal pain is one of the symptoms associated with coronavirus disease 2019 (Covid-19). The authors report the presence of acute pancreatitis in two of three family members with severe Covid-19 infection, excluding other causes of acute pancreatitis. All three cases were admitted to the hospital emergency department, with a positive test for SARS-Cov-2 RNA, developing acute respiratory distress syndrome. The first patient presented elevated amylasemia 11h after admission (>1500U/L), with evidence of acute pancreatitis on the abdominal ultrasound. The second patient complained of epigastric and periumbilical pain at admission. High amylasemia (>934U/L) was recorded 6 days after admission. In both cases The Modified Glasgow Acute Pancreatitis Score was 5 points, suggesting severe acute pancreatitis. The third patient presented respiratory distress and gastrointestinal symptoms, but showed no clinical and paraclinical signs of associated acute pancreatitis. These cases highlight acute pancreatitis as an associated complication of Covid-19 and mark the importance of measuring pancreatic enzymes in patients with SARS-CoV2 infections, especially if patients experience abdominal pain. DOES LONG PREOPERATIVE URETERAL DOUBLE J STENTING INFLUENCE THE OUTCOMES OF RETROGRADE URETEROSCOPY FOR URETERAL STONES? A MATCHED-PAIRED CASE-CONTROL STUDY (Abstract): There is a lot of debate about whether stenting is required or not prior retrograde semirigid ureteroscopy (URS). Moreover, the effect of long-term preoperative stenting on stone-free rate (SFR) and complication rate of URS. The **aim** of this study was to evaluate the effect of long-term preoperative double J stenting compared with non-stenting and recent pre-stenting on the outcomes of retrograde URS. **Material and methods**: The data of 90 patients admitted to the Urology Clinic of the Iasi "Dr. C. I. Parhon" Hospital between January 2017 and March 2020 were collected. The patients were divided into three equal groups, matched by age, sex, stone size and location: 30 non-stented patients, 30 patients stented three months before URS, and 30 patients with stents placed for over three months before URS. SFR and the rate of main URS complications (febrile syndrome and hematuria) were in the three groups were compared. **Results**: There were no statistical differences between groups in terms of SFR (73%. 77%, 80%, p = 0.6). The complication rate was similar in all three groups, for both febrile syndrome and hematuria. **Conclusions**: Long term preoperative double J stenting does not influence the SFR of retrograde semirigid URS. In all groups, the complication rate is very low and not influenced by preoperative stenting. **Keywords:** RETROGRADE URETEROSCPY, LONG-TERM PREOPERATIVE DOUBLE J STENTING, STONE-FREE RATE.

Retrograde ureteroscopy (URS) is a well-established method for treating ureteral stones (1). The success rate ranges from 79 to 97% for distal ureteral stones (2, 3), and 68 to 78% for proximal stones (4, 5, 6), with a general success rate of 84.5 to 94.2% (4). A method to improve the outcomes of URS may be the insertion of a double J stent before the procedure in order to dilate the ureter and facilitate the passage of the ureteroscope. Many studies have reported conflicting results, most authors stating that preoperative stenting helps improve stone free rate (SFR) and

lowers the complication rate (5, 6, 7, 8) no matter of stone size (less or more than 10 mm) (9), while others concluded that pre-stenting does not improve SFR (10, 11) and rises the likelihood of complications (12). Moreover, little information exists about the effect of long-term preoperative stenting, most studies being conducted in patients with short-term preoperative stenting (13, 14). That is why we conducted a study in which we compared the stone free rates and complications of 3 groups of patients who underwent long-term preoperative stenting, short preoperative stenting, and no-stenting, respectively.

MATERIAL AND METHODS

We conducted a retrospective match-paired case-control study of the patients admitted for URS to the Clinic of Urology of the Iasi "Dr. C. I. Parhon" Hospital between January 2018 and March 2020 (26 months). Data were extracted for patients' medical records. All URSs were performed with a semirigid *Olympus* ureteroscope, 8CH at the tip.

First, enrolled in the study were 30 patients with double-J stents inserted for over three months before USR: 10 with pelvic stones, 10 with iliac stones, and 10 with lumbar stones. The largest stone sizes ranged from 6 to 15 mm. In each 10-patient subgroup 5 had stones less or equal to 10 mm and 5 had stones over 10 mm in size. Then, 60 control patients were enrolled: 30 patients in whom a 6 to 8 CH preoperative stent were placed for infected hydronephrosis or persistent pain and 30 patients without preoperative stents. In each of the two control groups 10 patients had pelvic stones, 10 iliac stones, and 10 lumbar stones, also matched for gender, decade of life, and stone size with the study group. All patients were diagnosed with radiopaque stones by plain films, associated with urography and/or echography. SFR and immediate surgery specific complications (febrile syndrome, postoperative hematuria) were compared between groups. The febrile syndrome was defined as a temperature of over 38°C detected in the first 48 postoperative hours. Also considered was postoperative macroscopic hematuria developed during the first 48 hours after URS. The patients with no ureteral opacity on the plain films performed on postoperative days 1 or 2 were declared stone-free. The patients who could not be matched in one of the three above-described groups were excluded from the study. Also excluded were the patients with stones over 15 mm, multiple ureteral stones, radiolucent stones, calcified stents, or in which the stents were not placed or ureteral stones but for other conditions, such as: ureteral stenosis, neurological bladder, and neoplasms. Patients with incomplete medical records were also excluded. Enrollment was stopped when the number of 30 cases in each group was completed.

Statistical analysis. Because all three groups consisted of 30 cases, it was considered a normal distribution of data. Means and standard deviations (SD) were used for the description of quantitative variables. The *t-Student* test was used to compare the means and chi-square test to compare the proportions. For the differences in the means between the groups we used the ANOVA test for independent measures. To compare the results between the subgroups we used the Fischer test for small numbers and chi-square for more than 2x2 groups. All the results were considered statistically significant at $p < 0.05$.

We used the online statistics package socialstatistics.com.

RESULTS

The study included 90 patients who underwent URS, mean age of 57±16 years, with a predominance of females (57/90, 63.3%). Stones were equally located on the left and right side: 45 patients had stones on the right side and 45 patients had stones on the left side. Thirty patients had lumbar stones, 30 patients had iliac stones, and 30 patients had stones located in the pelvic segment of the ureter. In 45 patients stone size was no more than 10 mm and 45 patients had stones over 10 mm. According to the study design there were 3 groups of 30 patients each, having as a criterion of classification the presence or absence of a previously inserted double-J stent, and the patients with a stent were further grouped depending on the time of stent insertion (more or less than 3 months before URS). There were no differences between groups in terms of mean age, gender, stone location and side due to the study design. The demographic characteristics of the three groups are listed in first table.

TABLE I

Demographic characteristics of the three groups

	Group 1 > 3 months stent (n_1 = 30)	Group 2 No stent (n_2 = 30)	Group 3 <3 months stent (n_3 = 30)	p
Age (yrs.) mean ± SD	56 ± 15	54 ± 17	61 ± 14	NS
Female	19	19	19	NS
Left side URS	15	15	15	NS
Lumbar stone <10 mm/ >10 mm	5/5	5/5	5/5	NS
Iliac stone <10 mm/ >10 mm	5/5	5/5	5/5	NS
Pelvic stone <10 mm/ >10 mm	5/5	5/5	5/5	NS

The stone-free radiographic status was achieved by 69 of the 90 patients (77%). When SFR was compared between groups no significant differences were found between patients who underwent URS without stenting compared to those with stents placed for less or more than three months before the procedure (22/30, 73% *vs.* 23/30, 77% *vs.* 24/30, 80%, p=0.6) (tab. II).

SFR in the 3 groups ranged from 60% to 100% (no matter of stone size) but without statistically significant differences (70% *vs.* 70% *vs.* 80%, p = 0.8 for lumbar stones SFR, 60% *vs.* 60% *vs.* 80%, p = 0.6 for iliac stones SFR, and 90% *vs.* 80% *vs.* 100%, p = 0.4 for pelvic stones SFR). Also, the general success rates of URS did not achieve statistical significance in stones less than 10 mm (4/5 patients *vs.* 4/5 patients *vs.* 4/5 patients, p = 1.0 for lumbar stones SFR, 3/5 patients *vs.* 4/5 patients *vs.* 4/5 patients, p = 0.7 for iliac stones SFR, and 5/5 patients *vs.* 5/5 patients *vs.* 5/5 patients, p = 1 for pelvic stones SFR) or in stones over 10 mm (3/5 patients *vs.* 3/5 patients *vs.* 4/5 patients, p = 0.7 for lumbar stones SFR, 3/5 patients *vs.* 4/5 patients *vs.* 4/5 patients, p = 0.4 for iliac stones SFR,

and 4/5 patients *vs.* 3/5 patients *vs.* 5/5 patients, p = 0.4 for pelvic stones SFR). Ureteroscopic failures were due to the thin ureter which did not allow acute dilation and inflammation below the stone. In both situations, the ureteroscope could not be advanced up to the stone to allow lithotripsy. There was a single case, in group 2, in which a stone fragment migrated to the pyelocaliceal system thus the patient did not achieve the stone-free status. No severe complications, such as sepsis, or avulsion, were found. One case in each group had postoperative febrile syndrome, which was treated with intravenous antibiotics. Persistent postoperative hematuria complicated the disease course of 4/30 patients (12%) in group 1, 3/30 patients (10%) in group 2, and 3/30 patients (10%) in group 3 (p = 0.9).

TABLE II

Results and complications of retrograde ureteroscopy

	Group 1 > 3 months stent (n_1 = 30)	Group 2 No stent (n_2 = 30)	Group 3 < 3 months stent (n_3 = 30)	p
Total SFR	22/30 (73%)	23/30 (77%)	24/30 (80%)	0.6
Lumbar				
<10 mm	4/5	4/5	4/5	1.0
>10 mm	3/5	3/5	4/5	0.7

Complications				
Febrile syndrome	1/30	1/30	1/30	1.0
Hematuria	4/30	3/30	3/30	0.9

DISCUSSION

In our study there were no differences between groups in terms of the placement of a preoperative double-J stent and the timing of preoperative stenting. Our results agree with those reported by other researchers (10), finding no advantage in placing a double-J stent prior to URS. In practice many patients receive a double-J stent. This procedure is not justified by the facilitated ureteroscopic access before ureteral dilatation. Most patients are emergency cases and receive a double-J stent for pain relief or infected hydronephrosis. We believed that stents could help increasing the SFR, but our study failed to confirm that, as reported in the literature (15). Some studies reported more complications of long-term double-J stenting, such as calcifications or increased risk for sepsis (12, 16), while others did not (17). Our results support the harmlessness of preoperative stenting in terms of a greater risk for post-URS sepsis. Another interesting result was that there were no differences

in SFRs when stone locations (lumbar, iliac and pelvic) were compared. This finding disagrees with other studies which stated that SFR in greater in distally located stones (8). With thinner ureteroscopes, such as ours, advancement is possible without acute (18) or chronic (19) ureteral dilatation, explaining the similar results obtained in the non-stented group, compared with stented groups. Our overall SFR of 77% is lower than that reported by other authors (8, 9). The explanation for the results of over 90% SFR is that probably the patients were operated early in the course of the disease, thus avoiding inherent inflammation and edema around the calculi, which are known as factors hindering ureteroscope advancement. The postoperative complications were very rare in all three study groups, especially the febrile syndrome, probably because in all patients with urinary infections antibiotic therapy (second or third generation cephalosporins) was initiated at least 48 hours preoperatively. Another reason for this low incidence of the febrile syndrome is that we did not routinely apply high pressure fluid irrigation during surgeries, preferring to finish the procedure instead of forcing the high-pressure advancement of the ureteroscope, another reason for the low rate of iatrogenic ureteral injuries. Postoperative hematuria was a minor complication that remitted spontaneously in all cases. The stented patients had no more febrile syndrome or prolonged hematuria than non-stented patients, suggesting that stenting has no influence on URS complication rate (11), contrary to other studies in which stented patients had lower complication rates (5, 12, 8). The protective effect is probably due to other factors, including operator variability. If other urological departments reported an 8% pre-stenting rate prior to URS (20), in our department the majority of URSs are performed in pre-stented patients (21, 22).

CONCLUSSIONS

In our opinion, long-term preoperative double-J stenting before URS does not influence the SFR and incidence of complications compared with non-stenting and recent stenting, no matter of stone size and location.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

THE IMPACT OF TRANSCATHETER AORTIC VALVE IMPLANTATION IN PATIENTS WITH AORTIC STENOSIS (Abstract): Aortic stenosis (AS) is the most common valvopathy in elderly patients, with an increasing prevalence due to aging process of population, current guidelines recommending transcatheter aortic valve implantation (TAVI) as a choice of intervention**.** Frailty is an important predictor of outcomes in AS patients who undergo TAVI, but there is no consensus in its preoperative evaluation. **Aim:** to compare the clinical outcomes of TAVI with conventionally surgically treated patients. **Material and methods:** The data of all aortic valve procedures performed in over 65 years patients, treated at Cardiovascular Institute from Iasi (January 2015-September 2019) were analyzed. The propensity score was used to compare the prognostic of patients. **Results:** The target group included 70 patients referred to TAVI compared to a second group of 98 patients who undergone surgical aortic valve replacement (SAVR). The mean age of TAVI patients was higher than SAVR group (76.47 *vs.* 64.37). The heart failure associated with the valvular pathology was more severe in the TAVI group (61.43% patients included NYHA class III and 35.71% patients NYHA class IV) compared to the SAVR group (58.16% patients were NYHA class III and 7.14% patients were NYHA class IV). Atrial fibrillation was the most frequent arrhythmia found in both groups (13.57% TAVI and 41.11% SAVR). **Conclusions:** The present study highlights the place of TAVI in current treatment of high surgically risk patients with SA. **Keywords:** FRAILTY, AORTIC STENOSIS, TRANSCATHETER AORTIC VALVE IMPLANTATION, SURGICAL AORTIC VALVE IMPLANTATION.

The prevalence of elderly patients with cardiovascular (CVD) comorbidities is constantly growing due to both the demographic trend of population ageing (81 years old) and effective options for screening, prevention and management of potentially lethal diseases in middle-aged individuals (65 years). The incidence of CVD is estimated to increase from 40% in 40-59 years old patients to more than 70% among those over 65 years old (1).

In this context, a new concept was de-

veloped, frailty, which defines that category of patients, with limited physical reserves, multiple comorbidities and increased vulnerability to stressors (2). Frailty affects 10% of adults over 65 years old, with a high prevalence, up to 60% among those with cardiovascular disease (3). The frailty phenotype is evident in patients with degenerative aortic stenosis (AS), that affects mainly patients over 60 years old, reaching about 10% among patients over 80 years old (4). Conventional risk scores, such as Society of Thoracic Surgeons (STS) score and European System for Cardiac Operative Risk Evaluation (EuroSCORE) II are relatively accurate tools in estimating the risk of mortality in isolated SAVR but limited in TAVI due to a proven tendency of overestimation (5).

The aim of this study was to perform a comparative analysis of the profile and prognosis of patients who have benefited from TAVI with a comparable group of patients with surgical aortic valve replacement (SAVR).

MATERIAL AND METHODS

Study population

An unicentric, retrospective, cohort study was conducted in Cardiovascular Institute from Iasi in order to evaluate the early prognostic of patients with severe aortic stenosis who underwent TAVI admitted between January 2015 - September 2019 compared to a group of patients with the same pathology who underwent isolated SAVR with biological prosthesis. The control group was formed by correlating the propensity score. Patients were followed up for one year after the intervention with re-evaluations at 30 days, 6 months and 12 months.

We excluded from the study patients undergoing SAVR for aortic regurgitation and those with others concomitant cardiac procedures.

Study design and Endpoint definitions

To compare the differences between the outcomes of patients undergoing TAVI or isolated SAVR, a propensity score-matched analysis was performed.

To confirm the presence of a complication, the same parameters were used both in patients who underwent TAVI or SAVR:

- angina - the presence of one or more coronary lesions treated with medications, interventional or surgical revascularization,
- perioperative mortality - mortality occurred in the first 30 days after the intervention,
- postoperative AKI - increase in serum creatinine by over 150% compared to preoperative value or need for dialysis,
- stroke or transient ischemic attack - permanent or transient motor or sensory deficit,
- minor or major vascular complications - consistent with VARC-2 recommendations (6).

Statistical methods

Pre-, intra-, and postoperative information of the patients included in the study were introduced into a database using *Microsoft Excel* 15.20 for Mac OS X and were statistically analyzed using *IBM SPSS Statistics 24.0* program for Mac OS X. The results are presented as tables, graphical representations and dedicated statistical tests. Continuous variables are expressed as mean ± standard deviation. Categorical variables are expressed as total number of cases and percentages. Groups were compared using the χ^2 or Fisher exact test for categorical variables and the *ANOVA / Student's t-test* and *Wilcoxon-Mann-Whitney U / Kruskal Wallis* test for contin-

uous variables based on their distribution. Normality was checked using the *Kolmogorov-Smirnov* and the *Shapiro-Wilk W* tests. P-values <0.05 were considered significant.

The control group was selected based on propensity score matching (PSM) to remove the influence of confounding bias. PSM analysis was performed using logistic regression to create a propensity score for the TAVI and SAVR groups. Sex, BMI, age, and comorbidities were entered into the PSM, and the resulting score-matched pairs were used for further analyses.

The study was approved by the Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy, Iasi and the Ethics Committee of the Cardiovascular Institute from Iasi. The patients were informed about the study and signed an informed consent.

RESULTS

The study group included a total of 168 patients evaluated with AS with indications of valve prothesis, of which 70 patients underwent TAVI and 98 patients underwent isolated SAVR with biological valve. The demographic and clinical data of the patients are presented in first table.

TABLE I

Characteristics of the patient cohorts before matching

Parameter	TAVI	SAVR	p-value
Age (years)	76.47±6.83	64.37±11.76	0.002
Gender (no., % female)	37 (52.86)	41 (41.84)	N.S.
BMI (kg/m^2)	28.56±4.05	28.15±5.26	N.S.
EuroSCORE II	22.42±14.12	1.6±1.56	<0.001
AHT (no., %)	32 (45.71)	39 (39.79)	N.S.
NYHA (no., %)	NYHA II - 2 (2.86) NYHA III - 43 (61.43) NYHA IV - 25 (35.71)	NYHA II - 34 (34.69) NYHA III - 57 (58.16) NYHA IV - 7 (7.14)	< 0.001
Type 2 DM (no., %)	8 (11.43)	17 (17.35)	N.S.
AMI (no, %)	8 (11.43)	0 (0)	0.001
Stroke	5 (7.14)	5 (5.10)	N.S.
eGFR (medium) (mL/min)	78.33 ± 23.03	72.95 ± 15.83	N.S.
COPD (no, %)	12.86	12 (12.24)	N.S.
PAD (no., %)	10 (14.29)	7 (7.14)	N.S.
Hepatitis (no., %)	4 (5.88)	5 (5.10)	N.S.
LVEF (%)	53.88 ± 11.20	53.99 ± 11.12	N.S.
PPM	5 (7.14)	-	-
Prior cardiac surgery (no., %)	7 (10)	2 (2.04)	0.028
PH (no., %)	18 (25.71)	4 (4.82)	< 0.001

BMI-body mass index, AHT-arterial hypertension, NYHA-New York Heart Association, DM-diabetes mellitus, AMI-acute myocardial infarction, GFR-glomerular filtration ratio, COPD-chronic obstructive pulmonary disease, PAD-peripheral artery disease, PPM-permanent pacemaker, PH-pulmonary hypertension.

The TAVI patients were older compared to the SAVR group (76.47 ± 6.83 vs 63.37 ± 11.76 years; p = 0.002) and had a significantly increased surgical risk assessed by EuroSCORE II (22.42% ± 14.12 vs 1.6 ± 1.56; p < 0.001), these being two of the reasons why this therapeutic method was chosen. Previous cardiac surgery was a criterion for choosing TAVI, 7 (10%) of the patients having such a history, compared to 2 of patients treated with open heart surgery (2.04%). A number of 8 patients (11.43%) from the TAVI group had a history of acute myocardial infarction. The incidence of liver, kidney and chronic lung disease did not vary significantly between the two groups.

The transfemoral approach was preferred in 61 patients (87.14%), the valve implantation being performed in this way in patients without significant vascular lesions (iliac artery stenosis or occlusions, aortic aneurysm, atheromatosis with extensive parietal thrombosis and embolic risk). In 9 patients (12.85%), the valve was implanted by transapical approach due to poor ilio-femoral vessels. Overall, 48 TAVI patients had a SAPIEN 3 valve, and 22 patients had Medtronic CoreValve Evolut R. In the case of self-expandable (SE) valves, the most frequently used were those of 23 mm and 26 mm (60.41% and 29.16%) and for those balloon-expandable (BE), valves of 26 and 29 mm were used (54.54% and 45.45%). Valve under sizing was preferred in patients with extensive annular calcifications to prevent a possible rupture. Mild or moderate postprocedural valve regurgitation was identified in 17 cases (24.29%), the incidence decreasing at 6 months assessment. Relative to the total number of valves used, 9 of the SE valves (40.90%) and 8 of the 48 BE valves (16.67%) were associated with mild or moderate postprocedural regurgitation (tab. II). Although the incidence of regurgitation was almost three times higher with SE valves (p< 0.001), was not clinically significant.

The general postoperative morbidity and mortality of the two cohorts are presented in table III.

TABLE II

Risk of complications depending on valve rate

	Evolut R	SAPIEN 3
Regurgitation	9 (40.90%)	8 (16.67%)
Hemorrhagic complications	1 (4.55%)	6 (12.5%)
Vascular complications	2 (9.09%)	7 (14.58%)
PPM	1 (4.55%)	2 (4.17%)

TABLE III

Postoperative morbidity and mortality depending on the type of treatment

	TAVI	SAVR	p value
Acute kidney injury	10 (14.28%)	10 (10.20%)	N.S.
Postoperative AMI	0 (0%)	0 (0%)	N.S.
Infectious complications	7 (10%)	7 (7.14%)	N.S.
Stroke / TIA	0 (0%)	1 (1.02%)	N.S.
Hemorrhagic complications	7 (10%)	8 (8.16%)	N.S.
Postoperative arrhythmias	19 (27.14%)	45 (45.92%)	0.003
30-days mortality	5 (7.14%)	3 (3.06%)	N.S.

The most common arrhythmia found in both groups was atrial fibrillation (13 patients in TAVI group-13.57% and 37 cases in SAVR group-41.11%) (fig. 1). Four of the TAVI cohort developed atrioventricular block that required permanent pacemaker implantation (5.71%).

TAVI specific vascular complications were reported in 9 cases (12.86%) represented by: femoral artery stenosis treated with stent placement or endarterectomy with patch plasty (2), femoral artery rupture which required open surgical repair (2), pseudoaneurysm formation (2), access site bleeding and hematoma formation managed conservatively (1), vascular closure device failure which needed surgical suturing of the femoral artery (1), and iliac artery stripping resolved by femoral-femoral bypass (1). Severe vascular complications were registered in only 2 cases and were represented by an aortic dissection and annular rupture and lead to cardiac tamponade and hemorrhagic shock in both cases. Cardiac complications such as perforation of the right ventricle were recorded in only one case, the evolution being favorable under treatment.

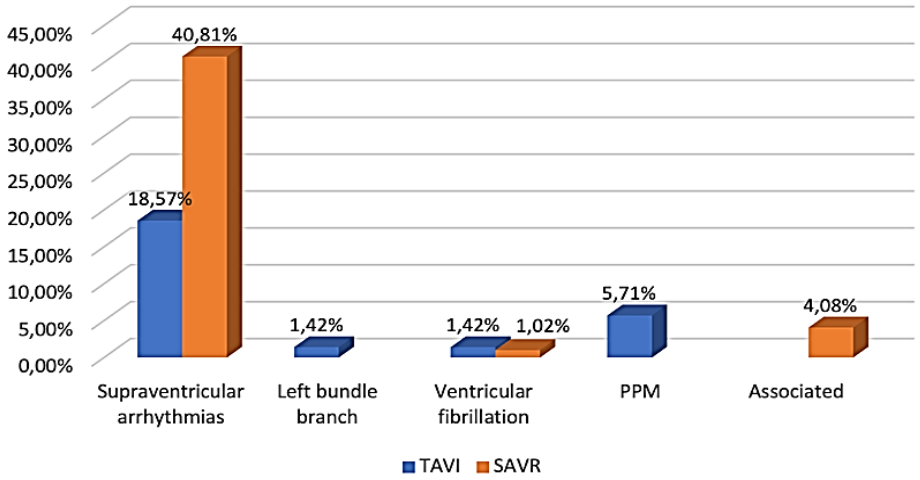

Fig. 1. Prevalence of postoperative arrhythmias

After surgery, 3 patients developed AKI, severe PH and upper gastrointestinal bleeding that led to death.

Considering the differences related to the risk profile, the SAVR group was analyzed after correlating the propensity score with the patients who underwent TAVI. From the total 98 patients with SAVR, 22 cases revealed similar preoperative profile to patients with TAVI based on PSM analysis, except EuroSCORE II. The value of EuroSCORE II could not be included because all patients treated surgically had a value below 3%, significantly lower than patients with TAVI. The obtained results are shown in table IV.

The length of post-procedural hospitalization in TAVI patients was 8.48% ± 7.28 days, but significantly shorter compared to surgically treated patients 16.10± 8.66 days.

TABLE IV

Postoperative morbidity and mortality depending on the type of treatment after correlation of the propensity score

	TAVI	SAVR	p value
Acute kidney injury	10 (14.28%)	3 (13.63%)	N.S.
Postoperative AMI	0 (0%)	0 (0%)	N.S.
Infectious complications	7 (10%)	3 (13.63%)	N.S.
Stroke / TIA	0 (0%)	0 (0%)	N.S.
Hemorrhagic complications	7 (10%)	4 (18.18%)	N.S.
Postoperative arrhythmias	19 (27.14%)	10 (45.45%)	0.003
Death < 30 days	5 (7.14%)	1 (4.54%)	N.S.

DISCUSSION

In the general analysis, the average age of patients treated with TAVI was 12 years higher compared with patients treated surgically (76.47 *vs.* 64.37 years). The surgical risk was significantly different, the average value of EuroSCORE II for patients with TAVI was 22.42% compared to 1.6% for the SAVR group. Only 4 patients with TAVI had an EuroSCORE II value < 10% compared to 96 of 98 patients with SAVR (5.71% TAVI *vs.* 97.95%). The maximum value of EuroSCORE II was 12.43% for SAVR and 54% for TAVI. Current studies show that patients who benefited from TAVI are older with multiple comorbidities and a prevalence of frailty of 63% (7, 8). TAVI was reserved for patients with a history of surgery and with multiple comorbidities, patients who could not have tolerated a conventional surgery.

The severity of heart failure was different, surgical patients being predominantly in NYHA class II and III (34.69% and 58.16%), in contrast to TAVI patients with advanced heart failure (61.43% in NYHA class III and 35.71% in NYHA class IV). Increased severity of heart failure caused the coexistence of PH in 25.71% of TAVI patients, compared to 4.82% of SAVR group.

In this study, the SE valves were associated with a higher rate of valvular regurgitation and the BE valve with several hemorrhagic complications. Vlastra *et al.*, reported a lower incidence of embolic accidents and pacemaker implantation by using transfemoral implanted BE valves (9), which was not found in our groups. The same research indicates an increased risk of bleeding complications in patients treated with BE valves, an observation that is in concordance with the results of our study. The SE valve was preferred in patients with a large aortic annuli given the availability of valves with a diameter of 34 mm compared to a maximum of 29 mm for BE valves. In the presence of extensive annular calcifications, was preferred the valvular under sizing, despite the risk of paravalvular leak or regurgitation.

Even if the rate of valvular regurgitation seems to be high (24.29%), the results are similar to those reported in the current literature, did not cause symptoms and recorded a regression on mild-term evaluation. The importance of this regurgitation is debatable given that the 2-year control performed in the PARTNER trial reveals a negative impact on survival (10). The incidence of regurgitation is lower in patients with SAVR due to the open surgical heart

procedure that allows the direct visualization of the valve, removal of cusps and annular calcifications and permits the direct measurement of the aortic ring. If the results are not satisfactory, implantation under direct visualization allows easy valvular repositioning. In patients with TAVI, the presence of extensive cusps or annular calcifications, correlate directly with the risk of paravalvular regurgitation, by quantifying the severity of calcifications on the preprocedural CT scans allowing accurate estimation of this risk.

The biological valves used in TAVI are different from those used in SAVR, resulting in lower pressure gradients which is associated with improved hemodynamic performance due to a larger orifice area (11). The technical differences between TAVI and SAVR explain the increased incidence of permanent pacemaker implantation in TAVI group, especially by using SE valves. In SAVR group, calcifications were removed, unlike TAVI group where calcifications are dislocated, leading to a potential injury of the atrioventricular bundle.

After correlating the propensity scores, although the results of comparison remained statistically insignificant due to the lower number of SAVR patients with similar TAVI comorbidities, in the TAVI group we found a lower incidence of infectious, hemorrhagic complications and postoperative arrhythmias compared to SAVR group. Indja *et al.*, showed in a recent meta-analysis a higher incidence of new-onset atrial fibrillation in the SAVR patients compared to the TAVI group. Furthermore, the study demonstrated that TAVI patients evaluated with atrial fibrillation after intervention had higher risk of stroke and mortality (12).

The value of EuroSCORE II was not used as a cofactor in the correlation of the propensity scores, the average value after correlation being 2.56% *vs.* 22.42% in the TAVI group, this situation was accepted due to the major difference in terms of risk profile would have determined the impossibility of obtaining a similar lot.

At the following reevaluation, there was a slight improvement in LVEF from 53.88% before the procedure to 57% one year after the intervention.

Acute kidney injury (AKI) is known as a common and serious complication after cardiac surgery (13). In our study, the incidence of AKI was lower (14.28%) than we expected under iodinated contrast injection. The absence of a significant difference between TAVI and SAVR could be attributed to a decreased renal perfusion during extracorporeal circulation in SAVR which contra balances the nephrotoxic effects of iodine in the TAVI group. Moreover, Kumar *et al.*, demonstrated that in patients with AS and chronic kidney disease, TAVI is a preferable approach being associated with a lower risk of AKI and dialysis requiring AKI and lower in-hospital mortality compared to SAVR (14).

Although the PARTNER study reports an incidence of stroke of 3.3% at 30 days after surgery (15), no case was observed in our study, careful selection of patients and approach, optimal progression of the implantation system through the blood vessels and good postoperative management of antiplatelet therapy have minimized this risk (0% in this case).

Wagner *et al.*, in a meta-analysis performed on 13 observational studies and 6 clinical trials, identified the association of

TAVI with low risk of major bleeding but with a high risk of vascular complications, moderate or severe paravalvular regurgitation and pacemaker implantation. In this study, paravalvular leak was reported in only 2 cases (2.86%) (16).

Even if TAVI patients revealed with multiple comorbidities, the length of post-procedural hospitalization was almost half compared to SAVR (8.48 days *vs.* 16.10 days), higher values being recorded in patients who developed complications, the obtained results being similar to the literature (17).

CONCLUSIONS

TAVI is a relevant therapeutic alternative to surgery in patients with a high operative risk. The mean age, prevalence of comorbidities and the value of EuroSCORE II are significantly increased in TAVI patients compared SAVR. TAVI performed in patients with an increased surgical risk is associated with morbidity and mortality rates similar to those recorded in patients with a reduced risk referred to SAVR. International guidelines include frailty as an indication of TAVI, but do not propose a precise tool for assessing it, further studies are needed to develop a general frailty score system applicable in current medical practice as an adjunct to prognostic scores in order to optimize preoperative status patients with subsequent improvement in prognostic and quality of life.

SARS-CoV-2 FULMINANT MYOCARDITIS:
AN AUTOPSY AND HISTOPATHOLOGICAL CASE STUDY

The new SARS-CoV-2 pathogen, causing coronavirus disease 2019 (COVID-19), was identified for the first time in December 2019, in China. Cases of COVID-19 have now been reported all around the world, resulting in 2020 in more than one million of deaths, which are consecutive in most of cases to a life-threatening acute respiratory distress syndrome (ARDS). Cardiovascular involvement can also occur, such as thrombosis or myocarditis, generally associated with pulmonary involvement. To date, little is known about SARSCov-2-induced myocarditis. Several cases of fulminant myocarditis have been reported, with only few cases of histopathological assessment. In the present study, it is reported a case of isolated fulminant myocarditis, including exhaustive post-mortem histopathological, immunohistochemical, and viral analyses (Gauchotte G, Venard V, Michaël Segondy M, *et al.* SARS-CoV-2 fulminant myocarditis: an autopsy and histopathological case study. *Int J Legal Med* 2021; 135: 577-581).

OCULO-AURICULO-VERTEBRAL SPECTRUM: CLINICAL FEATURES IN A COHORT OF 37 PATIENTS

OCULO-AURICULO-VERTEBRAL SPECTRUM: CLINICAL FEATURES IN A COHORT OF 37 PATIENTS (Abstract): Oculo-auriculo-vertebral spectrum (OAVS) is a developmental disorder involving structures derived from the first and second pharyngeal arches. The phenotype is clinically heterogeneous and is characterized by abnormal development of the ear, mandible, and defects of the vertebral spine. **Material and methods**: We performed a retrospective study on a group of 88 patients with various forms of external ear malformations and hearing loss. All patients were assessed for chromosomal abnormalities using karyotype and SALSA MLPA kits. **Results:** Of the 88 patients enrolled in the study, 37 (42.5%) were diagnosed with oculo-auriculo-vertebral spectrum based on clinical criteria. The main clinical findings were: microtia, preauricular tags and sinuses, epibulbar dermoids, mandibular hypoplasia, micrognathia, hearing loss and vertebral abnormalities. **Conclusions:** The causes, significant phenotypic heterogeneity, and variations in management make difficult creating evidence-based guidelines for diagnosis and management of this complex disorder. **Keywords:** OCULO-AURICULO-VERTEBRAL SPECTRUM, HEARING LOSS, EAR MALFORMATIONS.

Oculo - auriculo - vertebral spectrum (OAVS) is a heterogeneous disorder that affects the development of the ear, mouth, and mandible. It is characterized by facial asymmetry (due to hypoplasia of the jaw and/or mandible), abnormalities of the auricles and ear, and hearing loss; abnormalities of the inner ear, temporomandibular joint, and facial muscles may be associated. Malformations of the orbit, eye, nose, skull, neck, spine, or heart are also present, often unilaterally, but cases with bilateral involvement have been reported (1).

The spectrum ranges from mild to severe forms and includes: hemifacial microsomia, Goldenhar syndrome, oromandibular dysostosis, facial-auriculo-vertebral syndrome and lateral facial dysplasia (2). Goldenhar syndrome, which associated facial asymmetry, epibulbar dermoids, microtia, and vertebral anomalies, accounts for an estimated 10% of cases of OAVS (3).

The causes are still unclear and there are no widely agreed diagnostic criteria for OAVS. A proposed minimum criteria for the diagnosis includes asymmetric hypoplasia of

the facial structures with preauricular buds and/or microtia (4).

The prevalence of OAVS varies from 1/150,000 to 1/5,600, but an exact figure is difficult to estimate due to ethnic and geographic variability (5). Although the impairment is unilateral in most cases, approximately 10-15% are bilateral (6). Boys are more commonly affected, with a prevalence of 3:1, and unilateral impairment more often involves the right hemifacial region (4).

The American Cleft Palate-Craniofacial Association (ACPA) recommends that the management of patients with OAVS be performed by a multidisciplinary team including a pediatrician, audiologist, speech-language pathologist, oral surgeon, plastic surgeon, otolaryngologist, neurosurgeon, ophthalmologist, radiologist, psychologist, and geneticist. After cheilopalatoschisis, OAVS is the second most common congenital facial pathology that requires a multidisciplinary approach (7). Facial asymmetry caused by mandibular or maxillary hypoplasia is the main cause of craniofacial dysmorphia, dental malposition, and malocclusion (8).

MATERIAL AND METHODS

We performed a retrospective study on a group of 88 patients with various forms of hearing loss and external ear malformations. In all patients with positive family history, healthy first-degree relatives were included in the study if mutations were detected in the index case. Patients who met the minimal diagnostic criteria: unilateral microtia or various degrees of microtia, bilateral and asymmetric with facial asymmetry included. We considered skeletal involvement other than spine and ribs and symmetrical involvement of the auricles as exclusion criteria.

All patients enrolled in the study participated voluntarily and were registered under a code number to maintain anonymity. The use of the results was according to a protocol approved by the Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy from Iasi (approval no. 14789) and the Ethics Committee of the Children's Emergency Hospital "Sf. Maria" Iasi (approval no. 681). The patients, parents or guardians signed an informed consent form before the start of the study. All subjects were clinically evaluated by a geneticist.

DNA was extracted from 300 µL peripheral blood samples stored with EDTA using the Wizard Genomic DNA Purification Kit (Promega Corp., Madison, WI, USA).

All patients were assessed for chromosomal abnormalities using karyotype and MLPA technique (Multiplex Ligation-dependent Probe Amplification) using P036 and P070 for screening of subtelomeric region, P245-Microdeletion Syndromes which contain probes for common microdeletion/microduplication syndromes and P250-DiGeorge for 22q11.2 region (MRC-Holland, Amsterdam, The Netherlands) (9, 10).

MLPA analysis was performed according to the manufacturer's protocol. Briefly, 100 nanograms of genomic DNA were denatured and hybridized with SALSA probes at 60°C for approximately 20 h. After 15 min of ligation at 54°C, PCR was performed using Cy5-labeled primers. The fluorescent amplification products were separated based on their length by capillary electrophoresis in a CEQ 8000 GeXP Genetic Analysis System (Beckman Coulter, Brea, CA, USA), and the results were analyzed using the program Coffalyser. NET V9 (MRC-Holland, Amsterdam, The Netherlands). The probe ratio for deletion and duplication

was set to 0.7 and 1.3, respectively.

RESULTS

Of the 88 patients enrolled initially in the study, 37 (42.5%) were diagnosed with oculo-auriculo-vertebral spectrum based on clinical criteria, 17 (19.5%) with Treacher-Collins syndrome, and 10 (11%) with branchiootorenal syndrome; 24 (27%) with other syndromes or without clinical signs specific for a syndrome.

Of the 37 patients with the oculo-auriculo-vertebral spectrum, 17 of them had hearing loss and malformations of the external ear without other clinical signs. The male patients were preponderant with a sex ratio male: female of 2.7:1. The average age at diagnosis is 1 month, and approximately 80% of the included patients were diagnosed by the age of 1 year.

More than 50% of cases provided from pregnancy with parity >3 and 85% of patients from our study came from families with poor socio-economic situations. Prenatal history revealed that most patients included in the study (78% - 29 cases) had teratogen exposure (alcohol and/or antibiotics). A significant number of cases – 8 – were born prematurely; 6 of them had threatening miscarriage during pregnancy.

The main clinical signs present in our group are unilateral microtia 95% of patients, bilateral microtia in 2% cases, preauricular tags: 60% of patients, epibulbar dermoids: 30%, unilateral mandibular hypoplasia: 24%, micrognathia 15%, macrostomia 12% and preauricular sinuses 10%.

All patients included in the study have hearing loss: 33 of them have conductive hearing loss, while only 4 patients have mixed hearing loss. The main cause of addressability of these patients is hearing loss and malformations of the external ear (11).

The vertebral abnormalities were present in 15 cases, 12 of them had hemivertebrae, 2 vertebral blocks and 1 spina bifida. The occasional findings in our study include four cases with congenital heart defect, 1 case of epilepsy and 1 case of thalassemia minor.

Karyotype was normal in all cases, but MLPA showed 2 abnormal results: 1 patient had del22q11.22 between LCR D and LCR E genomic position 21.799.442-22.322.996 - hg19 and 1 patient had a deletion in exon 2 *DGCR8* gene chr22:20073612-20073613 -hg19.

DISCUSSION

The literature date indicated that phenotype in the oculo-auriculo-vertebral spectrum is variable from mild (with only hearing loss and possibly minor malformations in the external ear or mild asymmetry of the face) to severe (with complex malformations in the external ear such as vertebral, cardiac, genital, or nervous system anomalies) (12-14).

During the time were tried different attempts to classify abnormalities commonly associated with the OAVS. Thus, Vento and all. (15) elaborated OMENS classification, an acronym from **O**rbit, **M**andible, **E**ar, **NE**rve, and **S**oft tissues, while Horgan and all. transform OMENS acronym in OMENS plus by adding of extracranial damage (16). These classification systems were completed by Pruzansky and Kaban which focuses on the size and shape of the mandible and glenoid fossa. In theirs classification the grade I corresponds to mandibles with mild hypoplasia; grade IIa is associated with a functional hypoplastic and malformed condyles, grade IIb describes a severely hypoplastic and malformed condyles, with displacement from the temporomandibular joint, while grade III is represented by complete damage of

mandible, with the absence of the branch, condyle and joint (17).

External ear malformations, mandibular hypoplasia, micrognathia, hearing loss and vertebral anomalies are the most common features in our OAVS study (tab. I). A retrospective study of all patients referred for auricular reconstructive surgery during 1990-2012 (18), showed that atresia of the acoustic meatus, preauricular skin tags, hemifacial microsomia, and facial nerve palsy were present in most cases. All these clinical signs are present in the current clinical diagnosis criteria.

In our study sex ratio was male: female of 2.7:1 a little discordant reported to other studies. Bragagnolo *et al.* identified a 54% male cases from 72 patients (20), while Barisic *et al.* reported a male-to-female ratio of 1.4: 1 (19).

Although it cannot be proven concretely, recent studies propose the involvement of teratogenic factors, number of pregnancies and maternal age in the etiology of the oculo-auriculo-vertebral spectrum. Consistent with these, in our group 22% were first pregnancies but more than 50% of cases are multiparity (22). Werler suggests that twin pregnancies and those resulting from assisted reproduction are often involved in the etiology of the oculo-auriculo-vertebral spectrum. From our group, only 2 cases come from twin pregnancies and only one from assisted reproduction pregnancy, data inconsistent with the literature (23).

TABLE I

Prevalence of main clinical anomalies

Clinical findings	Our study N=37	Barisic *et al.* (19) N=259	Bragagnolo *et al.* (20) N=72	van Nunen *et al.* (18) N=155	Rooryck *et al.* (21) N=86
Microtia	95%	88%	100%	100%	70%
Preauricular tags	60%	45%	44%	12%	67%
Preauricular sinuses	10%	3%	3%	2%	7%
Epibulbar dermoids	30%	8%	15%	-	31%
Mandibular hypoplasia	24%	49%	94%	56%	76%
Micrognathia	15%	49%	76%	20%	22%
Hearing loss	90%	10%	45%	76%	68%
Vertebral abnormalities	40%	25%	8%	3%	35%

Although data from the literature suggest a higher frequency of premature births in patients with OAVS, in our group, 22% (8 cases) were born prematurely, 6 of them due to the threatening miscarriage during pregnancy (23). It was suggested that maternal diabetes may also be associated with OAVS (24) but in our study none of the mothers declared history of diabetes.

OAVS includes vertebral and spine malformations such as: hemivertebrae, vertebral blocks, scoliosis, or kyphoscoliosis, occipitalization of the atlas, and spina bifida. Identifying spinal abnormalities helps to manage neck pain, torticollis, spinal instability, or scoliosis (25-27). In our study, the main vertebral anomaly was hemivertebrae, identified in 12 cases.

Renkema *et al.* searched the nervous system abnormalities in the OAVS, and the most reported were neural tube defects, corpus callosum agenesis, intracranial lipo-

mas, Arnold-Chiari malformation, hydrocephalus, ventriculomegaly, cerebral hypoplasia and microcephaly (28). In these patients' intellectual disability is more frequent than general population, most commonly being present language development and neuro-psycho-motor delay. However, these features most likely present multifactorial causes, but frequently are found behavioral and social adaptation disorders caused by decreased self-confidence.

Ophthalmic abnormalities are common and include epibulbar or limbal dermoids, colobomas, orbital dystopia, or microphthalmia. Ophthalmological evaluation of limbal dermoids is indicated, with increased attention to astigmatism or anisometropia, management including excision and follow-up for the development of amblyopia. Epibulbar dermoids rarely require excision and are usually unilateral (25, 29-31). In our cases we found only epibulbar dermoids.

Although the group of patients with syndromic hearing loss represented by the oculo-atrial-vertebral spectrum presents clinical data consistent with the literature, in terms of genetic testing, we have only 2 abnormal results so far. The literature cites some promising arrayCGH results, but this complex test was impossible to apply to our patients (21).

First patient with abnormal MLPA result has a deletion of LCR D and LCR E segments in 22q11.22 region. Our patient had normal prenatal growth but preterm birth, with a gestational age of 37 weeks, nonspecific facial dysmorphic features (triangular face with arched eyebrows), conductive bilateral hearing loss and bilateral preauricular sinuses. Patients with this type of deletion have prenatal and postnatal growth restriction, behavior and neurological problems and cardiovascular defects (32).

The *DGCR8* gene deletion, found in another of our patients, is reported as a DiGeorge critical region, a gene whose haploinsufficiency can influence the severity of the clinical phenotype. Our patient, similar to those reported (33), had facial asymmetry with mandibular hypoplasia, multiple congenital anomalies, palatoschisis, hemivertebrae L2, malformed external ear unilateral and conductive hearing loss.

Regarding the audiological assessment, the early screening of the hearing loss helps in its treatment. Hearing is critical for language, social and cognitive development, and patients with OAVS are at risk of conductive or sensory hearing loss (34). Ear malformations, including microtia, atresia of the external auditory canal, and malformations of the eustachian tube cause conductive hearing loss. Malformations of the inner ear, vestibule, acoustic and facial nerve damage are usually associated with severe forms of OAVS and implicitly of hearing loss (35). Treatment of hearing loss is dependent on its degree, type and laterality and may include hearing aid, cochlear implantation, or surgical repair of the atresia of the ear canal (25).

In Romania, no studies have been performed on large groups of patients with syndromic hearing loss specially oculo-auriculo-vertebral spectrum. Data from the literature report a high incidence of these cases in disadvantaged families; these data coincide with our group, 85% of patients come from families with poor socio-economic situations. However, addressability of patients in rural areas is constantly increasing due to the possibility of material benefits in this pathology (36). Although attempts are being made to involve the social situation of patients in pathology, additional epidemiological and genetic studies are requested.

CONCLUSIONS

Oculo-auriculo-vertebral spectrum represents a complex craniofacial disorder that remains challenging for complete understanding. The causes, significant phenotypic heterogeneity, and variations in management make difficult creating evidence-based guidelines for diagnosis and management of this complex disorder. For the members of the craniofacial teams, this means the treatment of each individual patient is unique and different. Further research into the genetics is needed to help clarify the diagnosis.

To improve the quality of life and early treatment, it is necessary to develop diagnostic and management guidelines for cases of syndromic hearing loss.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

PSYCHOEMOTIONAL DISTRESS AT THE MEDICAL STAFF AFTER ONE YEAR PERIOD PANDEMIC IN A FIRST-LINE COVID-19 HOSPITAL (Abstract): Humankind is currently facing a pandemic of unimaginable proportions generated by a new strain of coronavirus, SARS-CoV-2, which causes significant public health problems. Material and methods: We employed a cross-sectional survey of 252 healthcare professionals from a frontline University Hospital in the "battle" with the new coronavirus after one-year pandemic. We analyzed the prevalence and associated factors with work-related psychological distress among our study group. Results: The results show that gender, marital status, the workload of treating COVID-19 patients, fear of SARS-CoV-2 infection, depression, and anxiety predicted burnout syndrome. Conclusions: The medical field is one of the most vulnerable areas where the staff is predisposed to psychological distress. This increases the probability of suffering different consequences, including burnout syndrome, depression, anxiety, post-traumatic stress disorder (PTSD). **Keywords:** PANDEMIC, BURN-OUT, PSYCHOEMOTIONAL DISTRESS, MEDICAL STAFF.

Burn-out is a syndrome defined as resulting from chronic workplace stress not successfully managed. It's a state of mental, physical, and emotional exhaustion caused by excessive and prolonged stress. It's a gradual process, first, the signs and symptoms are subtle (1).

There have been some pandemics throughout human history, infectious diseases often having devastating consequences. Plague, typhus, cholera, yellow fever, influenza, and tuberculosis are contagious diseases that have wreaked havoc over time. Nowadays, HIV infection could be considered a pandemic.

We are currently going through an exceptional period, with humanity facing a new pandemic, the SARS-CoV-2 virus infection (2). The spread of SARS-CoV-2 infection worldwide has been impressive. Today, we face more than 218 million diagnosed patients and an unknown number of people who have gone through the disease undiagnosed. Until now, there have been over 4,529,105 deaths worldwide. The first confirmed case in our country with

SARS-CoV-2 infection was on February 26th, 2020. Since then, over 1,098,765 cases have been confirmed, and over 3,570 deaths have been registered (3).

Given the developing circumstances with the new coronavirus, evidence synthesis about mental health outcomes it is necessary to produce guidance for professionals and health care facilities (4).

MATERIAL AND METHODS

According to the administrative zone health department's program report and plan, 252 healthcare professionals were working in the hospital at the time of the study that accepted to participate in our research. In addition, we obtained a list of healthcare professionals from the human resource department, and we excluded the persons on sick, annual, maternity, and family leaves.

We applied a questionnaire that contained general characteristics consisting of 11 items as follows: age, gender, marital status, education level, work experience, profession, number of rotating shifts within a month, socioeconomic status, satisfaction at work, current health condition, and behavioral factors (smoking, drugs, alcohol). Age details were collected as an ordinal variable; other questions were answered with values from 1 to 5. We also translated and adapted the *Hospital Anxiety and Depression Scale* (HADS). We used 21 items, seven about depression, seven about exhaustion, and seven about anxiety, with responses from 0 to 3.

RESULTS

Out of the entire hospital staff, 252 participated and completed the questionnaire, offering an overall response rate of 100%. The majority of participants were women (87.3% - 220). The average age was 38 years, ranging from 18 to 62 years old. The number of married participants was 1.2 higher than single participants. A high proportion of respondents had a bachelor's degree for higher education, 48.8%, high school graduates, 41.7%, and 9.5% of participants had secondary education.

As for the professional status of the participants, 35.73% are specialist doctors and resident physicians, nurses accounted for 35.31%, cares accounted for 9.52%, stretcher-bearers 4.36%, and the other workers accounted for 15.08% (economists, pharmacists, lawyers, psychologists, physiotherapists). Of all participants, 84.92% belonged to a job category that required interaction with COVID-19 patients, 84.12% perceived themselves as having a high or middle socioeconomic status. A total of 67% of participants were non-smokers, 5.15% stated that they occasionally consumed alcohol, none of them used drugs.

Regarding satisfaction at work, 32.93% declared they are satisfied and very satisfied. Of all participants, 34.54% claimed they have a good health condition, 41.66% medium, and 23.8% poor (tab. I)

As a result of the analysis of the data, aspects related to anxiety (21.03% - 53), exhaustion (17.46% - 44), and depression (11.9% - 30) are highlighted. We have noticed that overwork and burnout related to anxiety and depression are found among physicians and nurses.

There are main elements of anxiety and less psycho-emotional exhaustion among the medical staff with higher education at the beginning of their career (resident physician). In the context of this demanding period, the research focused more on psycho-emotional exhaustion and burn-out

syndrome. However, we want to emphasize that we can face challenges by activating defense mechanisms (coping / resilience).

In our study, no people were identified who could reach extreme exhaustion in the work process, on the one hand, due to good resilience and on the other hand, due to a well thought out program of work and rest and the possibility of supplementing the staff number during the pandemic by hiring nurses, carers, and stretcher-bearers for a determined period.

However, the psychological pressure at work, as well as the one felt after limiting and restricting mobility for shorter or longer periods, had an essential impact on the psycho-emotional state of health care workers, requiring further psychological reassessments and psychological support from the team sequentially at the end of pandemic and post-pandemic.

TABLE I.

General characteristics.

Variable	Value
Age (years old)	18-62 (average 38)
Gender	n=252
Female	220
Male	32
Marital status	
Married	105 (41.66%)
Divorced	30 (11.90%)
Widowed	12 (4.70%)
Single	45 (17.80%)
In a relationship	60 (23.94%)

Alcohol	13 (5.15%)

DISCUSSION

Pandemics of this magnitude have appeared in humanity about once every 100 years. Over the past decades, there has been an increasing belief that the experience of stress is associated with impairment of health (5).

The health care sector is one of the main sectors of the workforce, accounting for almost 10% of the European Union's workforce. The largest group of health workers are in hospitals. This sector has a significant imbalance between women and men; women account for almost 80% of employees. Psychosocial problems can lead to illness, accident, stigma, isolation, and death. They can also have a notable impact on the employer by lowering productivity and morale (6).

Resilience defines a person's ability to adapt quickly to problems /events with little stress. Resilient people do not reject their emotions but accept them without letting them take control or influence their decisions; for example, in the current situation, resilience can be seen as the ability to regain strength after specific changes or stressful events within the COVID-19 pandemic (7).

Coping designates any mechanism for prevention and adaptation to stress, any transaction between the subject and the environment to reduce stress intensity. Adaptation refers not only to living with anxiety. The coping mechanism is more general than the adaptation one. It aims to modify the system's functions to face the requirements of a dynamic environment and even eliminate the environmental factors that demand the new adaptation (8). There is an interconnectivity between stress, coping, and resilience so that exposure to stress brings about adaptation and triggers the adaptive mechanisms (resilience and coping) (9).

According to World Health Organization in 2009, mental health can be conceptualized as a state of well-being in which the individual is aware of his abilities, can cope with ordinary stressful situations in life, can work productively and fruitfully, can have a contribution to the community to which he belongs. In this positive way, mental health is the foundation of an individual and the community. This concept of mental health is consistent with its broad and varied interpretation of cultures (10).

Unfortunately, medical staff caring for patients with SARS-CoV-2 are often victims of this infection. Thus, 1 in 9 infected patients belongs to the medical staff. Any new disorder brings out the fear of the unknown, and the lack of information, conflicting data, or fake news can increase the perceived amount of stress by healthcare providers (11). Therefore, it is necessary to adapt and embrace policies that focus on correct dissemination of information, mutual support, and community-hospital relationships (12).

Health workers complain about accumulated fatigue and mental stress and suffer from burnout syndrome due to constant labor shortages and insufficient benefits. They can impact patients and colleagues as they have an increased risk of making wrong decisions and frequently quit their jobs because of extreme fatigue, exhaustion, fear of the unknown, fear of getting infected; many workers suffer from severe physical and mental stress, which leads to depression and trauma (1).

Psychosocial risks are related to the conception, organization, and management of work and the economic and social context of work, resulting in increased stress and severe deterioration of mental and physical health (13). Psychosocial work-related risk factors typical for the health sector include high expectations combined with time, skills, and insufficient social support; coping with pain; treating dying people, people with infectious diseases; emergencies; exposure to traumatic events; complaints and disputes (14).

Violence and harassment are also psychosocial dangers in the health sector. Violent behavior can come from patients, visitors, or colleagues. Health and social care sector reported the highest exposure to Violence at work in the European Union, 15.2%. In this sector, the incidence of

intimidation and harassment is above average (15).

The factors that determine the professional burnout of medical staff are death and suffering of patients; conflicts with colleagues and superiors; inadequate training; lack of social support; excessive workload; uncertainty about a prescribed treatment; pressure due to time; inadequate pay; conflict between career and family (16).

Health care workers are also at high risk for substance abuse due to specific risk factors such as exposure to a high volume of work, treatment of terminally ill and dying patients, inadequate training for work requirements, exhaustion, and insufficient knowledge of the dangers of alcohol and drugs, pandemic. All these psychosocial risk factors significantly influence employees' physical and mental health. Specific health problems caused by these risk factors may include stress, exhaustion, anxiety, irritability, depression (17).

We can prevent exhaustion syndrome by equitably calibrating the tasks assigned to the employee, periodic annual or biannual monitoring, communication, feedback, and setting new goals. Working in a hospital is challenging because employees usually need to handle intensive tasks involving work overload, extended working hours, high effort and energy, limited professionals, and lack of support, especially when we confront with this new virus when in the beginning, we didn't know how to protect ourselves and our family, how the virus affects us and when it will be gone (18). The global prevalence of psychological distress among medical personnel is high, providing that the threat posed by COVID-19 is a significant stressor for medical staff. Young employees should have better adaptability to the new condition represented by the pandemics than senior doctors (19).

CONCLUSIONS

Psychological stress is a natural phenomenon and can manifest in various forms. Every person is susceptible of it, being aware of this. Every person shows that he is attracted to balancing activities, even at work or home (20).

The existence of clear protocols for any possible situations, the practical training with the staff regarding the protection measures, the adequate use of protective equipment, and all actions that ensure a state of confidence and control decreases the stress level (21, 22). Understanding the challenges that doctors were facing, especially at the beginning of the pandemic, will help institutions provide psychological and organizational support. This pandemic raised an unknown social and economic problem that made the population adapt.

NEWS

SERUM FERRITIN AS A DIAGNOSTIC BIOMARKER FOR KAWASAKI DISEASE

Kawasaki disease is an acute febrile systemic vasculitis of unknown etiology. Kawasaki disease diagnosis depends on the use of adjuvant diagnostic markers, such as echocardiographic findings and laboratory biomarkers, including C-reactive protein, erythrocyte sedimentation rate, albumin, alanine aminotransferase, aspartate aminotransferase, white blood cell count, hemoglobin, platelet count, and pyuria. Although the laboratory findings observed in Kawasaki disease are not specific enough to conclusively establish a diagnosis, they can be useful, particularly in patients with a high suspicion for Kawasaki disease. Diagnosis of Kawasaki disease is occasionally delayed because it is solely based on clinical symptoms. Previous studies have attempted to identify diagnostic biomarkers for Kawasaki disease. Recently, patients with Kawasaki disease were reported to have elevated serum ferritin levels. This study aims to investigate the usefulness of the serum ferritin level as a diagnostic biomarker for distinguishing Kawasaki disease from other acute febrile illnesses. Blood samples were obtained from pediatric patients with Kawasaki disease and those with other acute febrile illnesses between December 2007 and June 2011 for measuring various laboratory parameters, including serum ferritin levels. In patients with Kawasaki disease, laboratory tests were performed at diagnosis and repeated at 2, 14, and 56 days after intravenous immunoglobulin treatment. At the time of diagnosis, serum ferritin levels in patients with Kawasaki disease (188.8 μg/L) were significantly higher than those in patients with other acute febrile illnesses (106.8 μg/L, P=0.003). The serum ferritin cut-off value of 120.8 μg/L effectively distinguished patients with Kawasaki disease from those with other acute febrile illnesses, with a sensitivity and specificity of 74.5% and 83.3%, respectively. Serum ferritin may be a useful biomarker to distinguish Kawasaki disease from other acute febrile illnesses. (Kim SH, Song ES, Yoon S, et al (2021). Serum Ferritin as a Diagnostic Biomarker for Kawasaki Disease. *Ann Med Lab* 2021; 41(3), 318322).

USING CASE-CASE STUDY DESIGN: WHICH CAN BE THE PERFORMANCE?

USING CASE-CASE STUDY DESIGN: WHICH CAN BE THE PERFORMANCE? (Abstract): The case-case studies compare groups of patients classified by the subtype of the disease they present, to identify specific risk factors for the sub-category of patients with a characteristic of interest. **Material and methods:** This analysis brings attention to the main characteristics of case-case studies, with the aim of facilitating the understanding of methodology and the adequate way of implementing it, and the interpretation of the obtained results. **Results:** Specifically, this study design identifies the differences regarding risk factors between disease's subtypes, reflecting their etiological heterogeneity. However, the association for potential risk factors that are common to comparison sub-groups cannot be identified and the risk revealed does not represent the risk level in the general population. One conducting a case-case study must consider both the characteristics of the chronic or infectious diseases category and the advantages and the limitation of this type of study. **Conclusions:** As advantages, the case-case study design helps minimizing the selection and recall bias and can be carried out for a shorter period of time, with fewer resources than conventional studies. Selection or information bias may persist, and caution is needed for the interpretation of results. **Keywords:** CASE-CASE STUDY, CASE-ONLY STUDY, BIAS.

Case-case studies are case-only epidemiological studies, a derived category from case-control studies which compares groups of patients classified by the subtype of the disease they present, in order to identify specific risk factors for the subcategory of patients with the characteristic of interest (genetic, histological etc.).

These studies are an alternative when population epidemiological studies cannot be carried out due to the unavailability of eligible participants or when resources are limited.

In general, epidemiological studies can explore only some of a disease's dimensions, having advantages and limitations in this regard. Therefore, an appropriate study design must be used to achieve the proposed objective, taking into consideration also the available resources, convenience, feasibility, costs, and ethical issues.

When none of the known epidemiological study designs allows the exploration of the disease's characteristics of interest, the design can be adapted in terms of the method (comparative groups, subject selec-

tion, statistical analysis) and measurement instruments.

The present analysis brings attention to the latest characteristics of case-case studies, with the final objective of facilitating understanding of methodology, how to efficiently perform it and how to correctly interpret the obtained results.

Case-case studies use as comparison group one of the disease's sub-category, to reflect the level of exposure in the source population, from which the cases originate. Because the comparison group also includes cases that have more frequent exposures to risk factors than the general population, it cannot represent the latter. Consequently, the measured association will not represent the risk of the disease in the general population.

As the exposure to risk factors is high in both the case and comparison groups, the potential association will be different from the one that might be revealed through classical (conventional) case-control studies. For the exposures that are very similar between cases and controls, the potential association will be masked or underestimated. However, if the risk factors are different between the comparison groups, the association can be easily identified, which suggests the existence of etiological heterogeneity.

Studying the chronic disease category

In the case of chronic diseases, the patients' belonging to one of the comparison groups can be identified with good accuracy by using genotyping (such as the presence of certain alleles), molecular characterization (for example the presence of cellular receptors), morphological characterization (histopathological aspects) or biomarker identification (1-4). In these studies, involving molecular tests, a gene-environment interaction (comparative analysis between genetic sub-categories) or the consequences induced by the causal factor (identification of a mutation, alteration of an intermediate marker etc.) can be revealed (4).

The errors in studies involving molecular biology data may be caused by differences in laboratory testing (laboratory method's complexity, inter-laboratory validity, working protocol), difficulty in identifying the errors, confounding factors, or misinterpretation of a biological marker significance (4). The presence of a factor associated with a disease (biomarker for molecular epidemiology) may represent an intermediate stage of a physiopathological process, or the consequence of changes induced by the causal factor and not the cause (4). At the same time, these types of studies use prevalent cases that may present a better survival, and the associated factor may be in fact a prognostic factor (4).

For the *cancer epidemiology*, the case-case studies can mainly identify risk factors, but also biomarkers of aggression (the risk of an aggressive subtype) or the risk of recurrence after treatment (1-3, 5).

For example, for *breast cancer*, a recent study identified an association between alcohol consumption and a lower risk for human epidermal growth factor 2-over expressing (H2E) receptors breast cancer compared to estrogen receptor positive (ER +) breast cancer (3). Regarding the aggressiveness of hormone receptor positive breast cancer (classified by histological grade and level of proliferation), in another study, an association was identified between nulliparity and highly proliferative (presence of K167 marker) tumors, obesity and high grade (poorly differentiated) tumors, and current use of combined hor-

mone therapy and low grade (well-differentiated) tumors (1, 5).

Another recent study on *prostate cancer* identified the SNPs (single nucleotide polymorphism) genes CYP17A1 (gene related to the synthesis and metabolism of steroid hormones), AR (androgen receptor gene), LHCGR (luteinizing hormone chorionic gonadotropin hormone receptor gene) and ESR (estrogen receptor genes) as biomarkers of prostate cancer risk, and rs743572, rs6162, rs6163 (in CYP17A1 gene), rs1256049 (in ESR2 gene) and rs2293275 (in LHCGR gene) variants as aggressiveness biomarkers (2).

Studying the infectious disease category

For infectious diseases, case-case studies can identify the source of contamination (or the route of transmission) for a rapid intervention to prevent the occurrence of new cases (6-9). Thus, in an outbreak investigation, the comparison group consists of non-outbreak cases, which were previously diagnosed and identified by the in-place surveillance system. As a result, the risk factor can have different significance between comparison groups and in consequence the real contamination source may not be identified, or the exposure may be very similar (over-matching) and the association underestimated (8, 10, 11).

In the case of comparative studies of infections caused by strains differentiated through the antibiotic resistance profile, phenotypically established, there is a risk for the low-level resistance expressing strains not to be identified and to be considered sensitive, causing cases' misclassification (9, 12, 13). Also, recall bias may be an issue when the assessment of exposures is recorded through patients' self-declaration (12).

The case-case comparison of different infectious diseases surveilled through passive systems, in which only a part of cases is registered, it will use only the selected cases, which are not representative for those present in the population (6). In this comparison, a selection bias can occur, if the cases' registration in the two surveillance systems are done differently, error that can be avoided by comparing the cases with the same disease caused by different strain subtype (characterized by phage profile, antibiotic resistance, plasmid profile) (6, 8, 11, 13, 14).

At the same time, the exposures may vary over time, and if the comparison is made with a control group identified in previous periods, the difference may be due to the dynamics over time and not to a real one (6). On the other hand, etiologically different infectious diseases may have some identical risk factors, which will not be identified through these case-case studies (11, 14). Sometimes, in the surveillance systems, the reported cases can mainly originate from clusters or only the severe ones can be declared, generating differences in the disease's severity among the compared groups (14).

As an overview, in order to use cases as a comparison group in the study of infectious diseases, they must originate from a sufficiently long surveillance period or from a sufficiently large population (cumulative national data) identified by a surveillance system which is stable over time and correctly records the exposures (6, 7).

When a case-case study design is envisaged, the main advantages and inconvenient should be considered to achieve a study with valid results (tab. I).

TABLE I.

The main advantages and limitations of case-case studies (1, 4, 6, 15).

Advantages	Limits
- Minimization simultaneously of the selection and recall bias - Short duration in time and less resources needed than population studies - Selectively identify the association between a particular exposure and a disease's sub-category - Useful for biomarkers identification and for the individual disease risk assessment improvement	- The found association does not represent the risk of the disease in the population - Selection or information bias may occur - Possibility for the two selected groups to remain not comparable - It cannot measure the association for factors that are common to both cases and the control group

CONCLUSIONS

The main advantage of case-case studies is the minimization of both selection and recall bias. They are useful for the rapid identification of risk factors, consuming fewer resources than other analytical studies. The method is however restrictive to study only a part of a diseases' risk factors, being appropriate for the identification of those that cannot be highlighted by population studies. The risk factors identified by these studies allow the description of a disease's etiological heterogeneity, but do not represent the risk of the disease occurring in the reference population.

The case-case study can increase the ability to exploit data collected in routine surveillance systems and complete knowledge about causality and natural history of a disease. Nevertheless, the interpretation of the results should be done with caution, considering the compared groups (aspects related to diseases or characteristics of compared patients) and the possibility of a selection and recall bias persistence.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

BIFIDOBACTERIUM LONGUM: PROTECTION AGAINST INFLAMMATORY BOWEL DISEASE

The prevalence of inflammatory bowel disease is generally associated with the change of the immune system and gut microbiota. Bifidobacterium longum is a symbiotic bacterium existed in the human gastrointestinal tract and has been demonstrated to be capable of relieving colitis in mice and can be employed as an alternative or auxiliary way for treating inflammatory bowel disease. Bifidobacterium longum can change the structure of the gut microbiota, induce and regulate immune responses, and reduce the expression of inflammatory cytokines and reactive oxygen species in the intestine. Besides, it can also maintain the normal intestinal barrier function by increasing the expression of the tight junction protein. Therefore, Bifidobacterium longum has great potential and can be used as a prevention, replacement, or adjuvant treatment for inflammatory bowel disease. (Yao S, Zhao Z, Wang W, Liu X. *Bifidobacterium Longum*: Protection against Inflammatory Bowel Disease. *J Immunol Res* 2021; 2021: 8030297).

EPIDEMIOLOGY PROFILE OF WEST NILE VIRUS MENINGITIS INFECTIONS IN NORTH-EAST OF ROMANIA

EPIDEMIOLOGY PROFILE OF WEST NILE VIRUS MENINGITIS INFECTIONS IN NORTH-EAST OF ROMANIA (Abstract): Meningitis is a disease with global presence that represents a worldwide issue, with the West Nile Virus as an etiological factor. The severity of viral meningitis depends on different factors such as age, immune system and etiological agents. **Aim:** The aim of the study was to study the frequency of West Nile Virus meningitis and to bring a contribution to the existing knowledge of the WNV distribution on adult individuals in Romania. **Results**: They showed a complete etiological and symptomatic picture for WNV meningitis with the main cause being the climatic changes experienced for the sudden appearance of an increased number of WNV infections. **Conclusions**: This retrospective study may constitute a foundation for a plan to prevent a possible epidemic of meningitis caused by the West Nile virus. **Keywords**: EPIDEMIC OF MENINGITIS, WEST NILE VIRUS

Meningitis represents inflammation of the protective membranes covering the brain and spinal cord, associated with abnormal number of cells in the cerebrospinal fluid (1, 2). Aseptic meningitis represents a syndrome characterized by acute onset of meningeal symptoms and fever, with pleocytosis of the cerebrospinal fluid and no growth on routine bacterial culture (1, 3). Viral meningitis can occur at any age but is most common in children (1, 4). In a large study by Rantakallio *et al.* comprising 12,000 subjects, showed the incidence of viral meningitis to be 219 per 100,000 in children under one year of age and 27.8 per 100,000 in children under 14 years old (4). A retrospective study with a small number of subjects showed that the incidence of aseptic meningitis in individuals aged 16 years and over is lower at 7.6 per 100,000 (5). Enteroviruses are said to account for 80% of cases in adults, but a wider range of causes is increasingly implicated. Often no cause is identified; among 144 consecutive adults with aseptic meningitis, only 72 had a confirmed diagnosis (5,6).

West Nile Virus (WNV) is an arthropod-borne flavivirus which is associated with epidemics of flu-like febrile illness usually associated with occurrence of men-

ingitis, encephalitis or acute flaccid paralysis (7). However only 1% of the infected people developed a neurological infection, exhibiting a mild illness with a fever-like headache, myalgias, nausea, vomiting and chills (8, 9-13). Around 5 percent of individuals with symptomatic WNV infection develop those neurologic diseases (14). But the percentage of the manifestation of invasive diseases can vary according to many factors such as endemics or season (7).

WNV meningitis presents symptoms such as: rapid onset of headaches, photophobia, back pain, confusion, and continued fever (8). Ordinary diagnostic tests include cerebrospinal fluid (CSF) to differentiate WNV infection from other infections that could give similar symptoms (8). Furthermore, after CSF other analyzes were performed based on this test, to accurately establish that these studied cases were WNV meningitis. Analysis methods such as blood count and PCR from blood and CSF. In addition to having at least one or more of the following symptoms: fever (temperature > 38°C) or hypothermia (temperature < 35°C); cerebrospinal fluid pleocytosis (>5 leukocytes/mm^3); peripheral leukocyte count >10,000/mm^3; or neuroimaging findings consistent with acute meningeal inflammation, reinforces the diagnosis of viral meningitis (7).

In this context, in the present paper we were interested in establishing some preliminary epidemiological profile of West Nile Virus meningitis infections in North-West part of Romania.

MATERIAL AND METHODS

We performed a retrospective study, including 29 patients diagnosed with meningitis caused by West Nile Virus, hospitalized during 2017 and 2018 in the "Sf. Parascheva" Clinical Hospital of Infectious Diseases, Iași county, Romania.

RESULTS

The study group consisted of 19 males (65.51%) and 10 (34.48%) females, mostly over the age of 61 (58%) and moderate amount of cases being between age of 21 to 40 (22.48%), coming mostly from rural areas (65.51%). The incidence of the studied cases occurred almost exclusively in the months of August (48.38%) and September (40.7%) (fig. 1).

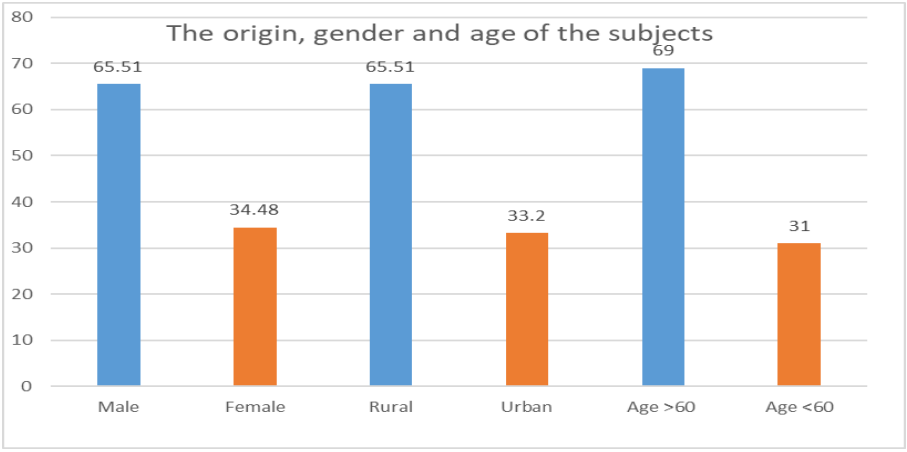

Fig. 1. Description of gender, origin and age

Of these cases, a number of 22 cases were reported with comorbidities such as: diabetes (16.12%), chronic hepatitis(16.12%), neoplasms (16.12%), CKD (9.6%) and cardiac pathology (12.9%) and for the rest there were no comorbidities (48.3%). A large proportion of patients did not use antibiotics (67.74%), but there are subjects who used a series of antibiotics before hospitalization such as: penicillins (16.1%), cephalosporins (9.6%), quinolones (6.45%).

Among the symptoms declared by the patients at admission, the most common was headache (70.96%), followed by confusion (54.83%), fever and other symptoms, with 1 to 7 days declaring the onset of the symptoms before hospitalization. Following the TGP enzyme biochemical analysis, the following values were observed: <40 (48.38%), 41-100 (25.8%), 101-200 (9.6%), 201-300 and >400 they both had the same number of cases (6.45%) and 301-400 with one case (3.2%) and the average value recorded was 99.25. The blood count analysis of the studied patients showed the following: leukocytosis (67.74%), normal number of leukocytes (32.25%) and no leukocytopenia (fig. 2).

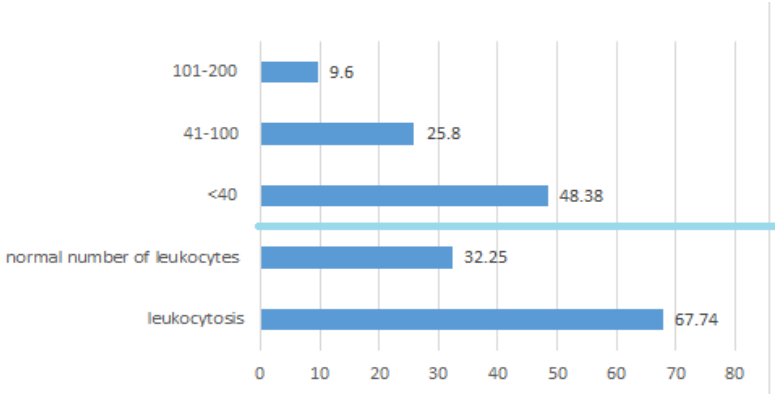

Fig. 2. Results of TGP enzyme and blood count analysis

PCR analyzes were also carried out on the cerebrospinal fluid (CSF) from the target group and the following results were obtained: age 0-10 (48.38%) followed by 21-30 (19.35%) a lower value was 11-20 (12.9%) and the values of 31-40 and >40 recorded the same percentage (9.6%). Adults over the age of 40 show the most positive results on PCR analysis, and children younger than 10 years show the fewest positive results.

The number of lumbar punctures was essential for carrying out laboratory analyses, all patients involved in the study had one puncture in order to collect cerebrospinal fluid (CSF).

For 74.19% a second CSF collection was carried out, and for 25.8 % a third harvest was necessary, the second and third were necessary because of unfavorable clinical-biological evolution or stationary. After the CSF collection, a CSF appearance test was performed, and the majority of it was clear (83.87%), followed by opalescent (9.6%), and hematic (6.45%).

The analysis of the number of CSF elements showed the highest value for <50 (41.93%), 101-200 (19.35%), value of 201-

300 (16.12%), for the number of elements 51-100 and 301-400 recorded the same number of 9.6%.

Following the analysis of the albumin value in CSF, the highest value recorded was for 1.1-2 g (52.61%), followed by 0.5-1g (26.39%) and > 2g (21%).

The CSF glucose value analysis showed a hyperglycorrhachia (98%) in the patients involved in the study (fig. 3 a, b).

a. CSF appearance test. **b.** Number of CSF elements

DISCUSSION

In the present article we traced the exponential increase for WNV meningitis, the study spanned a period of 2 years and presents major symptoms for West Nile Virus meningitis, all cases presented were specifically diagnosed with the West Nile virus. In the case of gender analysis, it can be noted that the occurrence of meningitis caused by WNV is higher in males (65.51%), compared to other viral agents WNV mainly affects adults, an aspect that is previously confirmed by other scientific sources (15). Seasonality is observable during the period of hospitalization of patients, predominantly from July to September. This season is usually characterized by a very hot dry weather, favorable for the proliferation of the viruses responsible for meningitis, which can also be observed in studies in the field (16).

Also recently, our research group become interested on the relationship between the West Nile virus and oxidative stress metabolism, as this was very rarely studied in the past. For example, it was showed that the WNV infection of rabbit PBMCs induces the transcription of HO-1 and inducible NO synthase (iNOS), suggesting that oxidative stress may be involved (17, 18). However, natural WNV strain infections do not induce stress granules (SGs) and some WNV strains could inhibit the SG formation induced by arsenite treatment (19).

The interaction of viral RNA and proteins with TIA-1/TIAR is found to interfere with the formation of SGs (20). Thus, WNV induced both ROS and the antioxidant responses. However, the infected cells do not display characteristics of oxidative stress since the antioxidant responses counteract the negative effects of ROS (19). Thus, it can speculate that the cellular redox status could be quite relevant for the life cycle of WNV.

CONCLUSIONS

In summary, the retrospective study carried out on WNV meningitis presents vital information regarding the spread of this

type of meningitis and the degree of incidence in the north-west area of the country for the period 2017-2018. These results may constitute important data for further development of prophylaxis methods against the spread of WNV meningitis.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

BREAST CANCER IN WOMEN YOUNGER THAN 35 YEARS OLD: IMMUNOHISTOCHEMICAL AND MOLECULAR CHARACTERISTICS AND IMAGING DIAGNOSIS (Abstract): The **aim** of this study was to characterize imaging, immunohistochemical and molecular breast cancer in women younger than 35 years old. **Material and methods**: In this retrospective study, data were collected from 46 patients under the age of 35, out of a total of 1,854 patients diagnosed with breast cancer between May 2012 and February 2019 at the Regional Institute of Oncology Iasi (Department of Surgery). The following tumor characteristics were evaluated: tumor size, histological type, molecular subtype, histological grade, nodal status and the presence of systemic metastases. **Results:** Of the 46 cases, invasive ductal carcinoma was the most common histological type (n=31, 67.39%). More than half of the tumors were ER + (n=36, 78.26%) and PR + (n=33, 71.73%). In 84.78% of cases (n=39) we observed a high expression of Ki67 proliferation index (> 20%). Luminal genomic B subtype was the most common (n=27, 58.69%), and triple negative breast cancer was 13.04% (n=6). **Conclusions:** Breast tumors in young women (under the age of 35) have a much more aggressive tumor biology. Future research is required to investigate new treatment strategies especially in young breast cancer patients. **Keywords:** BREAST CANCER, YOUNG WOMEN, AGE, LUMINAL.

Female breast carcinoma is one of the most malignant diseases in the world, with approximately 1 million newly diagnosed cases annually (1). In Romania, and in other developed or developing countries, breast cancer management is a major problem not only of the medical system, but also of the social and economic system.

Although efforts have been made by the EU in recent decades to implement mammographic screening programs (2), Romania is among the last places in Europe in terms of the rate of female population that has breast-controlled at least once in life. (3). Moreover, studies have shown that the mortality rate caused by breast cancer in Romania is 36%, much higher than the European average of 29% (3). In Romania, in 2017, 21 new breast cancers were diagnosed daily, and in the same country, the main cause of female mortality is breast cancer (every 3 hours, a woman dies from this disease) (3).

Starting from these premises, the prognostic factors are important not only in understanding the course of this disease, but also in predicting the outcome for each patient, and especially for choosing the optimal therapeutic management (4).

To date, numerous prognostic factors for breast cancer have been identified, including age, tumor size, degree of axillary lymph node involvement, histopathological grade (5), hormone receptor status (4,6-8), human epidermal growth factor receptor 2 (Her2) status (9, 10), or cell proliferation marker Ki67 (5). Thus, given the urgency of an individual therapy, the outcome in these cases should be estimated more accurately (9).

The aims of this study were to evaluate the clinical, imaging, immunohistochemical and molecular manifestations of young women with breast cancer.

MATERIAL AND METHODS

Patient selection

In this retrospective study, data were collected from medical charts of patients that had undergone surgical treatment between May 2012 and February 2019 at the Regional Institute of Oncology Iaşi (Department of Surgery). Out of a total of 1854 patients, we collected data on 46 patients, aged between 18 and 35 years old. The following tumor characteristics were evaluated: tumor size, histological type, molecular subtype, histological grade, nodal status, systemic metastases. All of these features were assessed according to the 4th edition of World Health Organization (WHO) Classification of Breast Tumors (11) and the 8th edition of the American Joint Committee on Cancer / Union for International Cancer Control (AJCC/UICC) Tumor-Node-Metastasis (TNM) Classification (12).

Also, we assessed the following immunomarkers: estrogen receptor (ER), progesterone receptor (PR), human epidermal growth factor receptor 2 (Her2/neu) and Ki67 proliferation index, in order to establish the subtypes defined into the framework of molecular classification of breast carcinoma (13). The immunoexpression of these markers was semi-quantitatively analyzed by using suitable scores reported in the literature. ER and PR were quantified according to Allred score (14). Her2/neu status was evaluated as per the standard criteria, on a scale from 0 (negative), 1+ (negative), 2+ (equivocal) to 3+ (positive) (15), and for equivocal results the silver-enhanced in situ hybridization method was applied (16). The Ki67 index was classified as high (> 20%) or low (≤20%) (17). Based on molecular differences primarily through gene expression and presence/absence of hormonal receptors on the cell surface, four clinically relevant breast cancer subtypes have been identified, including Luminal A (ER+, PR+, Her2-, Ki67 low expression), Luminal B (ER+, Her2-, PR-, or Ki67 high expression), triple-negative (ER-, PR-, Her2-), and Her2 (Her2 overexpression) (18).

Written consent regarding the usage of clinical and pathological data of the pa-

tients included in our study was obtained and approved by the Ethics Commissions of our Hospital (Regional Institute of Oncology, Iași) and the "Grigore T. Popa" University of Medicine and Pharmacy from Iasi Romania.

RESULTS

A total of 1854 women were diagnosed with breast cancer during this period, 46 youngers than the age of 35 years old. Of these, 4 of them had bilateral breast cancer and 6 patients had a hereditary - collateral history. Out of the very young group, 30 women presented palpable lesions and 7 axillary adenopathies on diagnosis.

Of the 46 cases, the histological type was: invasive breast carcinoma no special type (NST) (*n=31*), lobular (*n=3*), medullar (*n=3*), metaplastic (*n=1*), micropapillary + NST (*n=2*), cribriform + NST (*n=3*), tubular + NST (*n=2*) and apocrine + NST (*n=1*) (tab. I). The degree of differentiation for tumors (the degree of histological malignancy) evaluated according to the Nottingham scale allowed the tumors to be separated into: G1 invasive mammary carcinomas (*n=4*), G2 invasive mammary carcinomas (*n=13*), G3 invasive mammary carcinomas (*n=7*) and Gx invasive mammary carcinomas (*n=20*). The analyses of immunostaining for ER showed the presence of ER in 36 cases (78.26%) (fig.1.a), while the rest of 10 cases were negative for ER. Similarly, 33 of the cases (71.73%) were PR+ (fig.1.b) and 13 of the cases were PR- (28.27%). Each of the 46 immunohistochemically analyzed cases, were assigned to one of four phenotypes: classical phenotype ER+/PR+ (*n*=32), ER-/PR+phenotype- (*n*=8), ER+/PR-phenotype (*n*=3) and ER-/PR+ phenotype (*n*=3). The most commonly seen hormonal immunophenotype was the classical one with both receptors being present ER+/PR+. The interpretation of immunostaining of Her2 oncoprotein was done according ASCO-CAP recommendations, cases being classed as: score 0 (*n*=13), score 1+ (*n*=15), score 2+ (*n*=12) and score 3+ (*n*=6). The Ki67 proliferation index was significantly high in 39 cases (84.78%) (fig.2.a). The assignment of the analyzed cases according to Her 2 status was complete following in situ hybridization and showed 6 Her 3+ cases (fig.2.b) and 40 Her2- cases. The molecular subtypes revealed Luminal A (*n*=5), Luminal B (*n*=27), Her2/neu-type (*n*=8) and triple negative (*n*=6). All immunohistochemical and molecular characteristics can be seen in Table II.

All patients underwent imaging evaluations: ultrasonographic, mammographically examined and breast magnetic resonance (fig.3). On ultrasound examination, of the 40 patients examined, most patients (*n*=27) had tumors larger than 2.5 cm in diameter, and 13 patients had tumors smaller than 2.5 cm (tab. III). Multifocal masses were seen in 7 cases and microcalcifications without mass only in 5 cases. Also, 17 patients were mammographically examined, as well. Breast magnetic resonance imaging, performed in 3 cases, revealed: multicentric masses looking like invasive carcinoma and in situ (case 1), malignant expansive formation that associates the appearance of mastitis and deep axillary adenopathy (case 2) and mammary intraglandular expansive formation with indeterminate imaging characters, recommending corroboration with the anatomo-pathological examination (case3).

Regarding TNM tumor staging, the tumor size was T1 (*n*=15), T2 (*n*=20), T3 (*n*=5), T4 (*n*=4) and Tx (*n*=2). Similarly, the lymph node status was N0 (*n*=15), N1 (*n*=22), N2 (*n*=8), N3 (*n*=1) and Nx (*n*=0). The systemic metastases status was characterized as follows: M1 (*n*=1), M0 (*n*=10)

and Mx (n=4). Of the total 46 patients, 41 underwent Madden-type modified radical mastectomy, a surgical technique that involves the complete removal of the breast, including the overlying skin and nipple-areolar complex and ipsilateral level I, II axillary lymphadenectomy (19), while the breast conserving surgery with axillary lymph node dissection was preferred in 5 patients. 5 patients underwent breast reconstruction. Of the 46 patients, 30 cases underwent neoadjuvant chemotherapy.

DISCUSSION

In developed countries, breast cancer in people under the age of 40 accounts for 5-7% of all breast cancers (20). Moreover, in some countries such as China, the incidence of breast cancer in young women reaches 5-13% of all breast cancer cases (21). Various studies have shown that breast cancer in young women is different than in older women. Thus, these cancers in young women appear to have a more aggressive biological behavior, have a higher histopathological degree and a higher proliferation fraction, compared to older women (22). Also, breast cancer in young people has a worse prognosis in terms of recurrence and overall survival (23). Moreover, various authors have shown that young age is an independent factor of poor prognosis (24,25).

Of the 46 cases, invasive ductal carcinoma was the most common histological type, representing 67.39% (n=31), a result similar to Eric *et al.* (26). In his series of 79 women with breast cancer aged < 40 years, he observed that 70.9% pf patients (n=56) had invasive ductal carcinoma (26). Also, different authors have identified that invasive ductal carcinoma is one of the most common histological types of breast cancer in women under 40 years (7,27). Moreover, Copson *et al.*, in the largest prospective observational study evaluating the pathological characteristics of 2,956 women with breast cancer under 40 years, reported that the majority of tumors (86.5%) had ductal histology (28).

Currently, a more elaborate characterization of the interactions between immunohistochemistry and imaging is needed to understand not only breast cancer biology but especially the treatments adapted for each patient. Regarding breast cancer, ER and PR expression are considered the most useful predictive marker (5,29). Previous studies have shown ER expression in 50-80% of cases and PR expression in 60-70% of cases of invasive ductal carcinoma (5,30,31). Interestingly, some studies in India and Pakistan have shown a higher rate of hormone receptor-negative tumors than that found in the western population (29,32,33). In our study, ER+ status was found in 36 patients out of a total of 46 (78.26%). Also, PR+ status was observed at 71.73% (n=33). We remarked an important representation of estrogen and progesterone receptors.

Besides hormonal receptors, one of the most promising markers in breast cancer is Her2. This is a protein that is overexpressed in 18-20% of breast cancer and has been shown to have prognostic value (29-31). In this sense, Her2-expressing tumors are generally histologically high grade, tend to metastasize, and have a worse prognosis (34). The most common metastatic site for breast cancer is bone, being followed by lung, brain and liver (35).

According to ASCO-CAP recommendations, the cases in our study were classified as follows: score 0 (n=13), score 1+ (n=15), score 2+ (n=12) and score 3+ (n=6) (tab. II). In 8 (17.39%) of the patients we identified an overexpression of Her2/neu, overexpression that was reported as an aggressive immunophenotype in

breast cancer in young women (36). On the other hand, various authors have not identified a significant correlation of Her2/neu overexpression and young age in breast cancer patients (26,37).

Luminal A tumors are characterized by endocrine-responsive cancer (ER+, PR+) and low proliferative rate (low grade and low Ki67) (38) and have a better prognosis. Luminal subtype breast cancers also have the lowest recurrence rate, as opposed to triple negative subtypes that relapse the most (25,39,40). In our study, Luminal A tumors were in a small percentage of 10.86% (n=5) (tab. II). Similarly, Azim *et al.* reports that in his study, he identified Luminal A cancer in 17% of the younger and 35% of the older women (41). In another study of 46 women < 40 years and 73 patients > 40 years, Bouferraa *et al.*, observed that Luminal A subtype had a higher prevalence in patients above the age of 40, but the difference did not was statistically significant (42).

Luminal B tumors are also endocrine-responsive tumors but have a higher proliferative rate and have a worse prognosis compared to Luminal A tumors (38). In our study, we observed that compared to Luminal type A, Luminal B had a much higher prevalence rate of 58.69% (n=27), according to other studies in the literature, which reported a predominance of Luminal B tumors in young women and less often Luminal A tumors (43).

Triple-negative tumors (ER-, PR-, Her2-) usually have a very aggressive behavior, chemotherapy being the main pillar of treatment (44). We observed that in our group, triple-negative tumors were detected in 17.39 patients (n=8), according to other studies in the literature, which reported 19.9% in young women (28). Other authors have reported higher percentages, such as Carvalho *et al.* which identified a 25% rate (45) and Eric *et al.* which identified a 32% rate in the young women group (26).

The Ki67 proliferation index is a nuclear protein that is expressed in proliferating cells, being also a marker of tumor proliferative status (46). Although current guidelines from the American Society of Clinical Oncology do not include Ki67 as routine biological markers for breast cancer, however, in addition to ER, PR and Her2/neu status, Ki67 can complete the image of the histopathological pattern of the tumor. In this regard, new genetic tests have highlighted the role of proliferative genes, including the Ki67 marker, as a predictive factor (47). However, a standardization of Ki67 pathological assessment has not yet been determined (48).

In our study, of the 46 patients, 39 had Ki67 > 20%, and the remaining 7 had Ki67 < 20%. It should be noted that a significant percentage of patients (84.78%) had a high Ki67 proliferation index. In his study in which he compared the immunohistochemical characteristics of breast cancer in young women (< 40 years) and older women (> 60 years), Eric *et al.* observed that the Ki67 proliferation index was significantly higher in the young women group (26). Also, Fredholm *et al.* observed that in the group of young women (< 40 years), Ki67 was higher (> 14%) in a percentage of 79% in Luminal patients, 88.5% in Her2+ patients and 94.1% in triple-negative patients. Regarding the correlation of Ki67 value with tumor size, in our case we did not notice differences between Ki67 and tumor size. Thus, of the patients with Ki67 > 20% and which were ultrasound examined, 17 of them had tumors > 2.5 cm and 12 had tumors ≤ 2.5 cm.

Tumor size has traditionally been considered one of the most powerful prognostic factors in breast cancer (7,49,50). Moreover, this size of the breast tumor was

the basis of major staging systems for breast cancer (51-53). Some authors have reported increased tumor size as being associated with increased breast cancer-specific mortality with each joint estrogen and progesterone receptor status (54, 55). It is important to note that this information came from studies in which the authors located all stage T3 tumors (> 5 cm) in a single category (54, 55). On the other hand, the view that breast tumor size would correlate with survival in all breast cancer subtypes has been questioned (56), and several studies have found that this model is not valid for small breast tumors (57-59). In our study, we observed that there is no significant difference between tumor size and hormonal tumor expression. Thus, in the 40 patients explored ultrasonographically and ER+, 14 of them had tumors > 2.5 cm and 10 of them had tumors ≤ 2.5 cm (tab. III). Also, of the PR+ patients, 14 of them had tumors > 2.5 cm and 11 of them had tumor ≤ 2.5 cm (tab. III). In consensus, Zheng *et al.* obtained similar results, but piecewise (9). In his study of 358.870 female patients diagnosed with invasive breast cancer, Zheng *et al.* found that patients with 51-60 mm, 71-80 mm and > 80 mm tumors had similar breast-cancer specific mortality as those with 61-70 mm tumors. These results suggest in an interesting way that increasing tumor size potentially lost its prognostic value in ER+ PR+ group above the threshold of 51 mm (9). Sohail *et al.*, also observed that out of 59 ER+ patients, 22.3% had tumor sizes between 2-5 cm and 17.7% had > 5 cm. Also, of 48 PR+ patients, 18.5% had tumors between 2-5 cm and 15.4% had > 5 cm (5). In his study that included 19,541 non-Hispanic white women with node-negative breast cancer, Anderson *et al.* (54) observed that 80.3% (n=12,248) of ER+ tumors were ≤ 2 cm in size, while only 19.7% (n=2,999) were > 2 cm.

CONCLUSIONS

In our study of a group of 46 young women (under the age of 35) we identified an increased hormonal expression of estrogen and progesterone receptors, regardless of tumor size. We also identified Luminal B tumors in more than half of the patients, and a high Ki67 proliferation index. In conclusion, we believe that breast tumors in young women have a more aggressive tumor biology, and that future research is required to investigate new treatment strategies especially in this category of patients.

DEVELOPMENT AND VALIDATION OF A LC-MS/MS METHOD FOR THE QUANTITATIVE DETERMINATION OF TRAMADOL HYDROCHLORIDE (Abstract): The **aim** of this study was to develop and validated a highly sensitive, accurate, and precise liquid chromatography and tandem mass spectrometry (LC/MS/MS) method for quantitative analysis of tramadol (TMH) in human plasma using metoprolol tartrate as internal standard (IS). **Material and methods:** Quantitative analysis was done with methanol and 0.15 % formic acid in water (40:60, v/v) as the mobile phase and C_{18} as the stationary phase with a flow rate of 0.5 mL/min and MS as the detector. The mass spectrometer was operated in positive polarity mode. The method was validated for specificity, sensitivity, precision, accuracy, and other analytical parameters. The level of tramadol data was statistically analyzed using ANOVA at a 95% confidence level. **Results:** The total analytical run time was 2.5 min. The results found were satisfactory over the linear calibration range of 10-500 ng/mL for TMH. It is a simple, fast, precise and accurate liquid chromatographic method. **Conclusions:** The developed method can be used by scientific community for the quantification of tramadol in plasma samples from various clinical studies *of different dose strengths.* **Keywords:** TRAMADOL, LC/MS/MS METHOD, QUANTIFICATION.

Pain is the most common symptom of injuries, illnesses, disorders and conditions that we can experience throughout our lives. Depending on the type of pain, different medications may be recommended to relieve the discomfort. One of the most used drugs worldwide for alleviating moderate to severe pain is tramadol (TMH). It presents a very good analgesic activity by its action on central nervous system. Tramadol is considered a weak opioid due to its relatively low affinity for μ-opioid receptor, the main target for traditional opioids (1). It is available in a variety of formulations such as oral, suppository and parenteral preparations. The drug tramadol is a racemic mixture of two enantiomers in the form of hydrochlorides. The racemic

mixture of (+) dextro and (-) levo enantiomer of tramadol has synergistic analgesic effect. Some studies show that tramadol is also an effective antidepressant (2). Tramadol, in combination with adrenaline, has been used as a local anaesthetic in maxillofacial surgery. After oral administration it is rapidly absorbed from the intestine. Its oral bioavailability is 65–70 % due to first-pass metabolism (3) and it is metabolized to O-desmethyltramadol (ODT) primarily by cytochrome P450 (CYP) 2D6, and N-desmethyltramadol (NDT) by CYP2B6 and CYP3A4. ODT and NDT are further metabolized to N,O-dides-methyltramadol (NODT) by CYPs (4). Tissue distribution of tramadol is about 2.6–2.9 L/kg body weight. Tramadol does not have serious side effects, it is not addictive in therapeutic doses, as seen in other opioids such as morphine (5). Tramadol has been determined by using several chromatographic techniques such as liquid chromatography (LC) with ultraviolet (6, 7) or fluorescence detection (8, 9), LC coupled to tandem mass spectrometry (MS/MS) (10-12), gas chromatography (13, 14). Drug analysis is important in the pharmaceutical industry because it can help in dosage form selection by studying the stability of the active compound and identifying impurities in pharmaceutical formulations. Analytical determinations of medicinal substances are not only applied in the process of manufacturing medicines, but also in forensics for the quantification of prohibited substances in doping or problems related to drug abuse. This study aimed to develop a rapid, simple determination method for tramadol in human plasma using an isocratic LC-MS/MS.

MATERIALS AND METHODS

Materials

Tramadol hydrochloride (TM) and metoprolol tartrate as an internal standard (IS) were obtained from Unichem Laboratories LTD (India). HPLC-grade methanol, formic acid, and trichloroacetic acid were purchased from Merck (Germany). All other reagents were of analytical grade and commercially available.

Solutions

Stock solutions of tramadol (10 μg/mL) and IS (100 ppm) were prepared in methanol. Standard solutions of tramadol were obtained by the dilution of stock solution with methanol.

Sample preparation

0.5 mL biologic sample was treated with 0.5 mL trichloroacetic acid 5% like deproteinized. The obtained solution was ultrasonicated for 5 minutes and then centrifugated at 4000 rpm for 10 minutes. The supernatants were filtrated with a Millex-LH syringe filter (0.45 μm, 4 mm, Merck Millipore Ltd., Billerica, MA, USA) before injection into the LC. From the supernatant, a volume of 5 μL was measured and analyzed under the conditions of the method.

Chromatographic conditions

Tramadol and metoprolol tartrate in the sample were separated using a Dionex Ultimate 3000 LC instrument. Separation was performed using a Hypurity™ Elite Hypersil C18 (100 x 3 mm, 3 μm). The mobile phase consisted of methanol and 0.15 % formic acid in water (40:60, v/v). The flow rate was 0.5 mL/min, and the column temperature was set at 40 °C, and the autoinjector was set at 4 °C.

Mass spectrometric conditions

The column effluent was monitored using a triple quadrupole mass spectrometer (3200 QTRAP®, AB Sciex, Foster City, CA, USA) equipped with an electrospray probe in positive ionization mode. The ion transitions were monitored using a dwell time of 200 milliseconds for each compound: tramadol, 264.4/58.3; metoprolol 268.1/121.18. Samples were introduced to the interface through a turbo ion spray with the temperature set at 300 °C. A high positive voltage of 3.8 kV was applied to the ion spray. The pressure of the ionization gas was 20 psi, and the pressure of the auxiliary gas was 30 psi. Collision energy for tramadol and metoprolol tartrate was 1.5 mTorr. The capillary temperature was set at 320°C.

Method validation

In order to determine the *specificity* of the method, the following chromatograms were recorded under the method conditions:

- blank solution - 0.5 mL of a biological sample from each source (S1-S6);

- sample solution - 0.5 mL of a biological sample (S1-S6) was mixed with 0.025 mL standard solution of 40 ppm concentration;

- internal standard solution - 0.5 mL biological sample (S1-S6) was mixed with 0.025 mL solution 40 ppm internal standard solution.

Selectivity was studied by investigating the magnitude of any interference caused by drug metabolites. In order to establish the influence of interferences, a number of drugs such as metoclopramide, famotidine, granisetron, pantoprazole and fentanyl were co-administered with tramadol. It was considered: Metoclopramide - ESI (-) 301.0 → 190.0 (15), Famotidine - ESI (+) 338.3 → 189.2 (16), Granisetron - ESI (+) 313.1 → 138.2 (17), Pantoprazole - ESI (+) 384.1 → 200.0 (18), Fentanyl - ESI (+) 337.3 → 188.26 (19).

The study of the residual effect on the column

Analyte traces that can be found in the samples are identified by observing similar signals. These signals must have an area that does not exceed 0.2 of the lowest concentration in the studied range, and in the case of components that are internal standards must not be greater than 5%.

Solutions used:

- blank solution - a volume of 0.5 mL of biological sample;

- sample solution at the upper limit of quantification (ULOQ) - 0.5 mL of biological sample was mixed with 0.025 mL of the standard solution of 40 ppm concentration;

- sample solution at the lower limit of quantification (LLOQ) - 0.5 mL biological sample was mixed with 0.02 mL 1000 ppb concentration standard solution.

- internal standard solution - 0.5 mL of a biological sample (S1-S6) was mixed with 0.05 mL of 40 ppm internal standard solution, resulting in a solution with a concentration of 1000 ppb.

The formula used to calculate the residual effect is shown below:

$$\%\, residual\ effect = \frac{signal\ area\ (analyte\ blank\ solution)}{signal\ area\ \ (analyte\ sample\ solution)\ (LLOQ)} \times 100$$

Linearity. For the study of the linearity of the method, 3 sets of working solutions were prepared, on the concentration range 10-500 ppb for tramadol (20). The internal standard used for each solution was 1000 ppb metoprolol tartrate (tab. I).

TABLE I.
Linearity of the method

	P1	P2	P3	P4	P5	P6
TMH (ppb)	10	30	100	250	375	500
MT (IS) (ppb)	1000	1000	1000	1000	1000	1000

The precision of the method

It was established by determining repeatability and intermediate precision. A number of 3 samples were prepared and analyzed for each concentration level (10, 100, and 500 ppb). The concentration for each individual sample was calculated based on the equation of the regression line and the values of the areas corresponding to the tramadol peaks (21). The obtained values were processed statistically and the value of the coefficient of variation (CV) was calculated.

Accuracy of the method

Three standard solutions of tramadol with different concentrations (table II) were used in order to evaluate the accuracy of the method (22, 23). For each concentration, 3 series of determinations were performed, and the degree of recovery was calculated with the relationship:

$$\%\ Recovery = \frac{Calculated\ Concentration\ Value}{Nominal\ Concentration} x100$$

TABLE II.
The solutions for the accuracy study

	3xLLOQ	50%	ULOQ
TMH (ppb)	30	250	350

Time stability of the analyzed samples concentrations

The stabilities of TMH and IS in plasma were assessed by comparing the areas measured over 7-60 hours of storage at room temperature with the initial peak area (20, 22).

RESULTS

In order to establish the optimal parameters of the method, preliminary tests were conducted. We selected the chromatographic column (Hypurity™ Elite Hypersil C18, 100 x 3 mm, 3 µm) after assessing three types of chromatography columns. The mobile phases recommended by the specialized literature consist of a mixture of methanol or acetonitrile with buffer solutions such as phosphate, triethylamine, acetate, and formic acid with a pH between 2.5 and 7.3.

The results obtained in the study of the specificity of the method are shown in table III.

The chromatograms corresponding to the compounds considered for the evaluation of interferences are presented in first figure.

TABLE III
The study of the specificity of the method

	Standard	Retention time	Area at LLOQ		Area at ULOQ

DISCUSSION

The development of a practical chromatographic method for the determination of tramadol in human plasma is needed for clinical use. In our study, we used the MS/MS detection for tramadol because it possesses high sensitivity and selectivity. Ultraviolet detection from biological fluids is not suitable because of low sensitivity and selectivity (8). The LC separation of tramadol from a mixture using ultraviolet or fluorescence detection requires surfactants such as triethylamine and sodium dodecyl sulphate (9). These surfactants cause the ionic suppression of analytes in MS/MS analysis. The convenient ratio of the two solvents (formic acid : methanol) which provides good resolution was found

to be 40:60 (v/v). By changing this ratio, a decrease in peak area and height was found, and this would lead to a decrease in the sensitivity of the method. Other authors have used a mixture of acetonitrile - 0.1% formic acid 20 : 80 (v/v), as a mobile phase (8). The mobile phase consisted of methanol and a nonvolatile phosphoric acid salt solution was used by Ardakani *et al*. (24). The methods that are using a mobile phase with phosphate buffer are not suitable for MS/MS analysis.

In our experiments we followed the possibility of a simple procedure of processing samples, involving only deproteinization with 5% trichloroacetic acid. Other authors used for protein precipitation acetonitrile and methanol (25), or ethyl acetate (24). Using this procedure, the recoveries of tramadol in the present method were more than 89.9% while Ardakani *et al*. (23) obtained a recovery percentage of 80.8% and Tanaka *et al*. 85% (25). The run time for LC separation was shorter (5min) than in other studies (25, 26).

Analyzing table IV, it was observed the absence of signals that can be associated with interferents, and if they are present, then they are found in a concentration lower than 20% of the lower limit of quantification. Figure 2 showed that no interference occurred, due to the presence of the following substances: metoclopramide, granisetron, fentanyl, pantoprazole, and famotidine, administered simultaneously with tramadol.

In the column residual study, no residual signals were found for tramadol. For the control samples, no residual samples were found, after introducing the samples at the lower limit of quantification into the analysis (table V), as well as after using the samples at the upper limit of quantification.

The signals at the LLOQ for tramadol show a signal (S) to background noise (N) ratio of 712. On the other hand, the LLOQ value it must be a maximum of 5% of the ULOQ. In our case, it has 2% of the upper limit of quantification (table VI).

The calibration curve in human plasma of tramadol was linear over the concentration range of 10-500 ppb. Tanaka *et al*. reported a concentration range between 12.5-1600 ng/mL. The lower limit of quantification of tramadol was 10 ppb.

According to the data obtained and presented, the proposed analysis method is precise because the value of the coefficient of variation did not exceed 15% for the quality control samples, the maximum value being 7.42% (table VII). Other authors reported higher CV values for the precision study than in our case (12, 25).

The recovery of TMH was found to be in the range of 93.45-103.78%. These results show the proposed method is accurate. Complete data are shown in table VIII.

Analyzing the data in figure 4, the stability of the tramadol concentrations in the analyzed samples can be seen for 60 minutes.

CONCLUSIONS

We validated and applied a reverse phase LC method for the separation and quantitative determination, by mass spectrometry, of tramadol hydrochloride. The method was linear over the concentration range of 10-500 ppb tramadol hydrochloride. The value of the lower limit of quantification was at most 5% of the upper limit of quantification. The precision of the method estimated by repeatability and intermediate precision was below the 2% limit. The proposed method of analysis is accurate because the calculated concentration does not exceed 15% of the target values of the control samples. The shorter runtime allows the analysis of more sam-

ples. The method developed can be applied in drug analysis and control laboratories, toxicology laboratories, and for monitoring the concentration of tramadol in the blood. The developed method will be applied to evaluate the toxicity of tramadol on the human body as well as to evaluate the intensity of pain.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest.

EXPRESSION OF CYTOSKELETAL PROTEINS IN GLIOBLASTOMA CELL LINE (Abstract): The overexpression of vimentin is linked to tumors with low differentiation, metastatic diseases, and reduced overall survival. The precise function of transgelin, an actin-binding protein, in the development of cancer is still debatable. Nevertheless, its participation in the mobility, differentiation and programmed cell death of malignant cells has been well-established. **Material and methods**: To investigate transgelin and transgelin expression, we used glioblastoma U87 cell line 2D culture. We conducted immunofluorescence staining to examine cultured cells. **Results**: the studied proteins were co-expressed in the studied cell line. **Conclusions**: How transgelin is expressed in cancerous cells is similar to the expression of vimentin. This similarity could suggest that transgelin may serve as an indicator of the level of aggression in cancer. **Keywords**: VIMENTIN, TRANSGELIN, CANCER, CELL CULTURE.

Glioblastoma is the most common brain tumor, with a poor prognosis and survival rate. Despite the complex approach, including surgery, radiotherapy and adjuvant chemotherapy, most of the patients develop relapse of the disease in the first ten months after initial treatment (1, 2, 3).

Vimentin is a type III filament characteristic of mesenchymal cells coded at the level of chromosome 10p13 (4). In the adult body, it is found exclusively in specific cell types, namely fibroblasts, glial cells, endothelial cells and lymphocytes. Its roles include participation in the maintenance of focal adhesions, potentiation of lamellipodia formation through CARMIL2, and migration through interaction with actin (5, 6). Although they do not seem to be directly involved in cell motility, numerous studies have demonstrated that some intermediate filaments of the cytoskeleton, such as vimentin, affects the epithelial to mesenchymal transition (EMT), as well as on neoplastic cell invasion and migration (7- 9).

In neoplastic cells, vimentin seems to potentiate their migratory character by influencing cytoskeleton dynamic in EMT; its overexpression is correlated to poorly differentiated tumors metastatic disease and shorter overall survival (10 -12).

Originally named SM22alpha, trans-

gelin belongs to the calponin family, being an actin binding protein with multiple roles in cell dynamic and cell cycle. In the embryonic stage, the functions of transgelin are podosome formation and smooth muscle differentiation. In the adult, transgelin is found in the cytoplasm of fibroblasts and some epithelial cells, having a role in the regulation of smooth muscle fiber contraction, cell migration in response to inflammation, the formation of podosomes in smooth muscle cells and the reorganization of the cytoskeleton during cell differentiation (13, 14).

In the context of carcinogenesis, the role of transgelin is controversial, although its participation in the processes of migration, differentiation and apoptosis of neoplastic cells is known(15). Data from previous research cannot establish a pattern of transgelin's expression in cancer; studies performed on tissue samples and cell lines exert contradictory results, as transgelin being overexpressed in colorectal (16), lung (17) and hepatocellular cancer (18).

In other ways, there are some evidence of transgelin being under expressed in prostate(19), esophageal (20) and cervical cancer (21) .

The role of transgelin as a tumor marker cannot be discussed as long as it may found in significant amounts in normal tissue. To fully comprehend the role of transgelin in the spread of cancer, its function must be studied thoroughly. This will allow for an evaluation of its potential role in determining the prognosis of the disease. The exact mechanism through which transgelin operates on cancer cells remains unclear, but it is believed that it results from a modification in the expression of genes that regulate cell mobility (22).

MATERIAL AND METHODS

We investigate vimentin and transgelin co-expression in glioblastoma U87 cell line.

Cell cultures

To investigate transgelin and transgelin expression, we used a glioblastoma U87 cell line cultured in 2D system. The cells were provided by the University of Bergen, Norway with the support of Mr. James Lorens.

Cell line was cultured in DMEM/F12 medium supplemented with 10 μg/mL of insulin 5% horse serum, 20 ng/mL of EGF, 0.5 μg/mL of hydrocortisone, 100 ng/mL cholera toxin, 100 U/mL of penicillin and 100 μg/mL of streptomycin (Sigma-Aldrich, St. Louis, MO, USA). We used 96-well culture plates which were incubated at 37°C for seven days.

Immunofluorescence

We performed fixation of the plates with 4% paraformaldehyde for 1 h then we washed them with PBS at room temperature for 5 minutes. A solution containing 0.3% saponin, 0.3% Triton X 100 and 0.3% digitonin was used for permeabilization.

The process of permeabilization was exclusively conducted on cytoplasmic targets, namely vimentin and transgelin. Primary antibodies, vimentin (Monoclonal Mouse anti-vimentin Clone V9) (1:25) and transgelin (rabbit SM22 Alpha (1:25) were diluted with Dako antibody diluent and left to incubate for 72 hours at a temperature of 4°C. Afterward, cells that were labeled for vimentin and transgelin underwent two washes with PBS, each lasting for five minutes. Following this, they were subjected to a 24-hour incubation with Alexa Fluor 647 goat anti-mouse (1:200) and FITC anti-rabbit (1:200) before being observed. To protect the dyes, they were incubated

overnight at a temperature of 4°Celsius with Prolong (R) Gold antifade with DAPI.

Analysis

In order to acquire images in digital format at 20x, the TissueFAXS 4.2 software (provided by Tissue Gnostic) and the Zeiss Axio Observer Z1 microscope were utilized.

The analysis of the markers under investigation was conducted using Histo Quest 6.0 software, which expresses the average of the "sum intensity" of the fluorescent signal for each cell.

Research ethics. The research was conducted with the authorization the Institutional review board (IRB) approval from Regional Institute of Oncology (No. 108/ 29.03.2023).

RESULTS

To evaluate the levels of transgelin and vimentin expression, a glioblastoma cell line was utilized.

We conducted immunofluorescence staining to examine cultured cells.

The stained material was captured through digital imaging fluorescence microscopy. In the examined cell line, both transgelin and vimentin were simultaneously expressed, as shown in first figure.

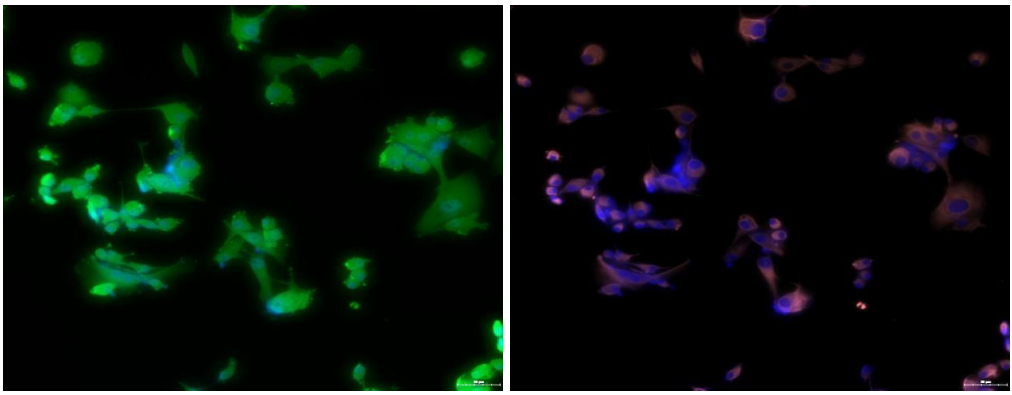

Fig. 1. Transgelin (green) and vimentin (pink) co-expression in U87 glioma cells. Pictures were acquired at 20X.

DISCUSSION

As a component of an extensive research project, this particular section focuses on transgelin and vimentin co-expression in a malignant cell line. It is an essential fragment of the project as a whole, and its findings will contribute significantly to the overall conclusions.

The focus of our research is on the expression of transgelin in an in vitro 2D culture system in relation with the expression levels of vimentin. Our findings reveal that transgelin is co-expressed with vimentin in malignant brain cancer cells.

Studies conducted in the past have demonstrated that inhibiting the function of vimentin in mice leads to the suppression of smooth muscle development and impediments in the process of scarring (6, 23). In recent years, vimentin has been recognized as a marker of EMT, a complex process that is often related to cancer spread. This is of particular importance in the context of cancer because the acquisition of a mobile

and invasive phenotype is associated with the development of metastases, which is the primary cause of death for cancer patients (8).

The involvement of vimentin in cancer cells infiltrating their surroundings is a subject of interest in the field. Understanding the role of this protein in the process of cancer cell invasion could have significant implications for the development of treatments, as its role in chemoresistance is already established (24).

In presented data, the expression of vimentin is explained by the invasive, aggressive character of glioblastoma cells. Nevertheless, a two-dimensional cell culture model would not be able to exhibit the identical progression pattern as a prototype in vivo. The primary outcome deduced from results provided should center on the co-expression of vimentin and transgelin, with both serving as possible indicators of an invasive and aggressive cellular behavior.

The represented results may vary from cell line to cell line and could be also different from in vivo studies; glioblastoma is a very heterogenous pathology, with cellular and molecular diversity not only between tumors but also within the tumor (25). Co-expression of transgelin with a well-known poor prognosis factor as vimentin may indicate a potential similar role in cancer biology. Results may also vary from type of cell line or used tissue samples, as shown before. Immunofluorescence transgelin staining sustain previous research of transgelin being expressed in aggressive cancers (26). The expression of transgelin and also its functional role appear to contrast across different tumor cell types and stromal tissues and may be potentially modified due to various factors such as microenvironmental conditions, gene expression or even cancer progression (27).

CONCLUSIONS

As cancer pathology continues to be a significant global issue, there is a strong conviction that fresh insights into the conduct of cancer with regard to invasion and metastasis are crucially required.

The expression of transgelin in cancer cells appears to resemble that of vimentin, implying that it may function as an indicator of cancer aggressiveness.

Despite conflicting data in the literature, our study of transgelin expands the knowledge base. Specifically, we aim to enhance our comprehension of the part transgelin plays in the invasion and spread of cancer, with potential implications for treatment modalities in clinical settings. Additional research is required to validate the co-expression and correlation of vimentin and transgelin with cancer metastasis.

CONFLICT OF INTEREST AND FUNDING

The authors have officially stated that there is no conflict-of-interest present in their scientific research. Additionally, they have confirmed that they received funding specifically by “Grigore T. Popa” University Medicine and Pharmacy, Iasi, Romania Grant No. 12444 from 27.06.2017. Cell lines were provided by Mr. James Lorens from University of Bergen, Norway.

BLOOD PRESSURE LOWERING EFFECTS OF CENTRAL TNF-α BLOCKADE DEPENDS ON FUNCTIONAL LEPTIN SIGNALING (Abstract) **Background**: Obesity is a major independent risk factor for the development and progression of arterial hypertension. Leptin-mediated sympathoexcitation is a common phenomenon in obesity. Since leptin leads to the synthesis of Tumor Necrosis Factor (TNF)-α in the central nervous system, we hypothesized that the pathological activation of the sympathetic nervous system in obesity-associated hypertension may be mediated by central leptin-related TNF-α mechanisms. **Material and methods:** We compared the long-term effects of TNF-α inhibition on mean arterial blood pressure, heart rate, baroreflex sensitivity and sympathetic tone in animals with a functional leptin signaling (i.e. lean Zucker rats - LZR) and in animals insensitive to leptin (i.e. obese Zucker rats - OZR). **Results:** central inhibition of TNF-α in normotensive LZR significantly lowered mean arterial blood pressure, decreased sympathetic activity and improved baroreflex sensitivity but not in the OZR group. **Conclusions:** These findings suggest that a functionally central leptin-TNF-α signaling plays a key role in mediating the central sympathetic outflow and may represent a promising approach to ameliorate the pathophysiology of obesity related-hypertension. **Keywords:** OBESITY, LEPTIN, TNF-α, HYPERTENSION, BAROREFLEX SENSITIVITY.

Arterial hypertension is a significant contributor to cardiovascular morbidity and mortality worldwide, and the activation of the sympathetic nervous system has been shown to play a key role in its pathogenesis (1-4). Obesity is a major independent risk factor for the development and progression of arterial hypertension, as obese individuals often have excessively high levels of renal and muscle sympathetic nerve activity due to pathological sympathoexcitation (2, 3, 5). The excessive activation of the sympathetic nervous system has been demonstrated as a crucial mechanism in the development of obesity-induced hypertension. By counteracting the activation of the sympathetic nervous system, pharmacological and non-pharmacological sympatholytic therapies have been shown to lower blood pressure in obesity-associated hyper-

tension (3-7). Leptin-mediated sympathoexcitation is a common phenomenon in obesity, with various central mechanisms such as the melanocortin system or phosphoinositide 3-kinase (PI3K) signaling pathways playing a key role (6, 8). Additionally, TNF-α-leptin mediated mechanisms may also contribute to the pathological activation of the sympathetic nervous system, as leptin leads to the synthesis of TNF-α in the central nervous system, which subsequently causes sympathoexcitation and high levels of arterial blood pressure (9-11). Peripheral TNF-α may also contribute to an increased sympathetic activity in obesity-associated hypertension, as shown in both clinical and experimental studies (10). Furthermore, sympathetic activation and hypertension in such physiopathological settings are associated with impaired baroreflex control of heart rate. At the level of the nucleus tractus solitari, leptin impairs baroreflex control of heart rate in response to increase in arterial pressure (12). Moreover, central TNF-α impairs baroreflex sensitivity and increases arterial blood pressure and heart rate (13). Thus, our aim was to test the hypothesis that the pathological activation of the sympathetic nervous system in obesity-associated hypertension is mediated by central leptin and TNF-alpha. Therefore, we compared the cardiovascular responses to TNF-α blockade with etanercept in animals with a functional leptin signaling and in animals insensitive to leptin. To investigate whether leptin-TNF-α induced sympathoexcitation is driven by central or peripheral mechanisms, we administered etanercept both peripherally and centrally.

MATERIAL AND METHODS

All procedures were performed considering the reduction of animal distress and minimizing as much as possible the number of the animals for statistical significance. Six adult male obese Zucker (*fa/fa)* rats and six littermate lean Zucker rats (28-32 weeks of age) were used. Rats were housed in a temperature (21-23°C) and humidity-controlled environment with a 12 h light/dark cycle, with *ad libitum* access to food and water. All procedures involving surgical intervention were conducted under isoflurane anesthesia (2-3%). All experiments were performed in accordance to the European Directive 2010/63/EU on the Protection of Animals Used for Scientific Purposes, the European Convention for the Protection of Vertebrate Animals used for Experimental and other Scientific Purposes (Council of Europe No. 123, Strasbourg, 1985) and the National Institutes of Health Guide for the Care and Use of Laboratory Animals and were approved by the Research Ethics Committee of the "*Grigore T. Popa*" University of Medicine and Pharmacy, Iași.

Continuous Blood Pressure Recording

For continuous measurement of blood pressure a telemetric system was used as previously described (14). Briefly, the body of the telemetry transmitters (*TRM54PB, Millar, Inc., Houston, TX, United States*) was placed intraabdominally and secured to the abdominal wall. The tip of the pressor sensor was inserted into the femoral artery and advanced into the abdominal aorta below the emergence of the renal arteries. At the end of the implantation procedure all the incisions were closed with non-absorbable sutures (*3-0 Prolene; Ethicon, NJ, United States*) and antibiotic prophylaxis administered intraperitoneally was continued for 72 hours.

Continuous Recording of BP Waveform

Using a PowerLab 16/35 acquisition system (*ADInstruments, Bella Vista, NSW,*

Australia), 24-h blood pressure waveforms from implanted telemeters were acquired continuously at a sampling frequency of 2000 Hz . TR181 smartpads (*Millar, Inc., Houston, TX, United States*) were used for both blood pressure signal acquisition and wireless charging of the implanted telemeters. Daily mean arterial pressure (MAP) and heart rate (HR) were calculated from all 24-hrs individual cardiac cycles identified using LabChart® built-in BP module (*ADInstruments, Bella Vista, NSW, Australia*) as previously described (14).

Peripheral and central inhibition of TNF-α

Peripheral inhibition of TNF-α was attained by daily intraperitoneal administration of Enbrel® in doses of 5 mg/kc as reported by others to have a proper TNF-α inhibition (15). For central TNF-α inhibition we have used osmotic minipumps (Alzet model 2002, pumping rate ± 0.5μL/hr) connected to a stainless steel 23 G canula which was inserted into right lateral cerebroventricle using a stereotactic system (*Stoelting Co, IL, USA*). Continuous intracerebroventricular administration of Enbrel® was made in doses of 10 μg/kg/day which were reported in other studies to have a proper central TNF-α inhibition (16). Briefly, after isoflurane anesthesia, the head of the rat was gently fixed into stereotactic apparatus and a longitudinal incision was made on the middle line of the skull. A small hole was drilled at the following coordinates: bregma -0.84 mm; lateral + 1.8 mm; depth + 4.3 mm and the 23 G stainless steel canula was inserted into the right lateral cerebroventricle. The osmotic minipump was inserted subcutaneously and connected to the infusion cannula via the catheter tube to deliver etanercept into the right lateral cerebroventricular. After anchoring the canula to the cranium with dental cement, the incision was closed with stainless steel clips (*Stoelting Co., Wood Dale, IL, United States*).

Estimation of Sympathetic Activity

As we previously described (17), the original daily BP signal sampled at 2000 Hz was analyzed in the frequency domain using the implementation of the LabChart® software based on the Fast Fourier Transform algorithm. Power spectra were calculated for all artifact-free segments ~1 min in duration, overlapping by 50% and windowed using a Hamming function and finally averaged to generate daily BP spectra. Analysis of the direct BP signal was preferred over extraction of cardiac cycle-related variables such as the systolic BP as it avoided the inherent issues related to resampling for unequally spaced time-series (17). Since the frequency band between 0.25 and 0.75 Hz (low frequency, LF) contains BP oscillations originating from sympathetically driven variations in arterial vascular tone (18), the power in this band was integrated and expressed as percentage of the total power below the HR (0.01-3 Hz).

Time-domain analyses

The sequence technique was used to calculate spontaneous baroreflex sensitivity from the slope of the linear regression functions between SBP and the subsequent PI of the following 3rd, 4th and 5th heartbeat , as we have previously described (17). Up and down sequences of at least three intervals with changes in SBP of >1 mmHg and in PI of >0.5 msec were analyzed only if the correlation coefficients were > 0.85.

Statistical Analysis

Results are expressed as mean ± SE. One-way repeated measures ANOVA followed by Dunnett's multiple comparison test were used (Prism 6.01, GraphPad Software) to indicate the presence or ab-

sence of statistical differences between groups.

RESULTS

Responses to peripheral inhibition of TNF-α

As shown in Fig. 1, obese Zucker rats (OZR) are hypertensive while lean Zucker rats (LZR) are normotensive. Although there is a significant difference between mean arterial pressure (MAP) in LZR *vs.* OZR (105 ± 3 mmHg *vs.* 116 ± 3 mmHg), peripheral TNF-α inhibition did not induce any changes in either group. Heart rate (HR) significantly differs, LZR showing an increased heart rate when compared to OZR as shown in figure 2. No difference of baroreflex sensitivity (BRS) between LZR and OZR was observed during the control period. Baroreflex sensitivity in LZR increased after intraperitoneal administration of etanercept, but this effect did not reach statistical significance. No changes in baroreflex sensitivity were observed in the OZR during peripheral blockade of TNF-α as shown in figure 3. As shown in figure 4, the degree of the estimated sympathetic activity is higher in OZR compared to LZR during control period and no other significant changes were observed during peripheral inhibition of TNF-α.

Responses to central inhibition of TNF-α

The MAP significantly decreased in LZR during central inhibition of TNF-α achieved by continuously intracerebroventricular administration of etanercept. No significant changes were observed in the obese group, the values of the MAP being comparable to those from control period (fig. 1). HR was maintained approximately at the same levels during the entire period of continuously intracerebroventricular administration of etanercept for both groups (fig. 2). In the LZR group, the BRS was significantly higher during central TNF-α inhibition. Conversely, in the OZR the BRS was slightly lower at the end of the intracerebroventricular administration of anti-TNF-α (fig. 3). The activity of the sympathetic nervous system significantly decreased during central TNF-α inhibition but only in the LZR group (fig. 4).

DISCUSSION

The major findings of the present study are: 1) central inhibition of TNF-α in normotensive LZR, with functional leptin signaling, significantly improved BRS, decreased sympathetic activity and lowered MAP and 2) in the hypertensive OZR which are insensitive to leptin, TNF inhibition fails to lower sympathetic tone, did not improved BRS and did not lower MAP.

A state of low-grade chronic inflammation is considered a feature of obesity and is characterized by secretion from adipose tissue of various inflammatory adipokines such as resistin, monocyte chemoattractant protein-1, leptin, interleukin 6 (IL-6) and TNF-α (19-21). Leptin was shown to be involved in mediating inflammatory cytokines through the activation of dendritic cells, monocytes and macrophages (22-25). Experimental studies have demonstrated a close relationship between leptin and TNF-α production through various pathways such as phospholipase D1 (26), p38 mitogen-activated protein kinase (p38 MAPK), c-Jun N-terminal kinase (JNK) (27) or activation of human B cells via Janus activation kinase 2 (JAK2)/ signal transducer and activator of transcription 3 (STAT 3) signaling pathways (28). In the OZR, the TNF-α adipose expression starts around 3 to 4 weeks of age when usually the animals are already obese and insulin resistant (29, 30). The level of TNF-α expression is correlated with the degree of adiposity and the associated metabolic disturbances (30). Since systemic inflammation is known to impair cardiovascular homeostasis, we hypothesized that peripheral TNF-α may represent the linking mechanism between inflammation and cardiovascular dysregulation in obesity related-hypertension. Although OZR have high levels of circulating and tissue TNF-α (31,32), in our study its peripheral inhibition did not improved cardiovascular parameters since BRS, MAP or vascular myogenic sympathetic tone did not change. These results suggest that peripheral TNF may be involved in hypertensive organ damage, systemic inflammation, endothelial dysfunction, rather than in the physiopathology of sympathetic obesity-related hypertension.

When centrally administrated in normal rats, leptin was shown to increase sympathetic outflow through pathways within ventromedial hypothalamus which result in high levels of plasma norepinephrine and epinephrine concentrations (33). Other experimental studies have shown that intracerebroventricular infusion or microinjection of leptin into the arcuate nucleus induces sympathetic activation to various territories such kidneys or lumbar nerves and subsequent increase of arterial BP and alteration of BRS (34-36). Additionally, Bin Yu *et al.* have shown that increased concentrations of central leptin and TNF-α play a key role in the development of obesity-related hypertension (37). Moreover, in obese mice, Han et coworkers have shown that central leptin-induced TNF-α production was associated with high levels of diurnal blood pressure values, suggesting that this mechanism may contribute to obesity-related hypertension (9). Also, central TNF-α inhibition over the short-term reduced arterial blood pressure and heart rate suggesting that leptin-TNF-α interplay may play a critical role in the physiopathology of obesity hypertension (9). Also, in a model of renovascular hypertension, central TNF-α inhibition reduces blood pressure, restored baroreflex sensitivity and sympathetic tone (38). Taken together, these results strongly support the hypothesis that central leptin-TNF-α may play a key role in obesity-related hypertension.

The results from our study suggest that over the long term, leptin-TNF-α mediated central sympathetic activation is functional under normal conditions and is responsible for maintaining a basal physiologic sympathetic tone, as shown in LZR. This mechanism might become hyperactive in obesity when leptin increase and lead to subsequent sympathoexcitation and hypertension. This hypothesis is supported by the results from OZR with an altered leptin signaling mechanisms in which central TNF inhibition did not lower arterial blood pressure or sympathetic tone. On the contrary, in LZR with a functional leptin signaling, TNF-α inhibition significantly improved BRS, decreased sympathetic tone and lowered MAP. Although is still a matter for further investigations, our results suggest that central leptin-TNF-α signaling may represent a promising approach to ameliorate the physiopathology of obesity related-hypertension.

CONCLUSIONS

These findings suggest that a functionally central leptin-TNF-α signaling plays a key role in mediating the central sympathetic outflow and may represent a promising approach to improve the pathophysiology of obesity related-hypertension.

IMPLICATIONS OF CHRONIC ILLNESS AND ACADEMIC STRESS ON STUDENT QUALITY OF LIFE (Abstract): The present study had two main aims, namely to identify differences between the quality of life of students with chronic illness compared to that of students without significant health difficulties and to identify significant predictors among academic stressors. **Materials and methods:** Data were collected between May and July 2023 using an instrument consisting of The World Health Organization Quality of Life-BREF and Academic Stress Scale from 257 students, of whom 52 had a diagnosis of chronic illness and 202 did not. **Results:** there were significant differences according to the presence or absence of chronic illness in psychological health [$t(255) = -2.569$, $p = 0.011$], physiological health [$t(255) = -5.502$, $p < 0.01$] and social relationships [$t(255) = -2.640$, $p = 0.009$]. Among subjects with a chronic illness, two significant predictive models were identified, the first is composed of the predictor self-perceptions ($F(1, 54)=23.62$, $p<.01$), and the second from the predictors self-perceptions and time limits ($F(2, 54)=16.27$ $p<.01$). Among subjects without a chronic illness three statistically significant predictive models were identified, the third strongest being made up of self-perceptions, pressure to perform and time limits ($F(3, 201)=40.00$, $p<.01$). **Conclusions:** the quality of life of students with chronic illness is significantly lower compared to that of students without chronic illness. In addition to the fact that students' quality of life is impacted by academic stress driven by self- perceptions and time limits, that of students without chronic illnesses is additionally impacted by pressure to perform. **Keywords:** QUALITY OF LIFE, CHRONIC ILLNESS IN STUDENTS, ACADEMIC STRESS.

The prevalence of chronic disease among students is increasing, with this population facing a number of particular challenges in the university environment (1, 2). The best-known definition of quality of life is one that focuses on a person's subjective perception of their position in life in the context of culture and value system where they are inserted, which also involves their goals, perspectives, standards and concerns (3). As a result, quality of life can be impacted by many factors, including chronic illness and academic stress.

Chronic illness causes negative effects on students' quality of life as well as their academic performance (4), compared to students without chronic medical condi-

tions who perform better on both variables (5). Moreover, unlike their healthy peers, students with chronic illness are more likely to receive state aid and are less likely to graduate and find employment (6).

In the study conducted by authors Wilson and Spencer (7), 95% of students indicated that their chronic illness had at least a moderate impact on the psychological dimension of quality of life, with 81% estimating that they felt anxious or depressed at least once a month because of their health condition.

Accepting the limits imposed by the body on academic performance causes students, in addition to the need to reformulate goals and standards, frustration and disappointment (8). In addition to sometimes losing control over their own bodies, chronically ill students also experience feelings of losing control over their social lives (9). Thus, in general, students with a chronic condition not only have a lower health-related quality of life, but they also report higher levels of loneliness and isolation (5, 6).

Stress, academic stress in particular, has been identified as having serious implications for students' physical and mental health (10). In the present study, we aim to extend the literature by identifying the link between various academic stressors and quality of life among students with chronic illness.

In the face of these problematic situations, students with chronic illnesses tend to use maladaptive coping mechanisms, such as dissembling, ignoring and humiliating, and ignoring symptoms, which ultimately magnify their difficulties (8, 11). Such trends observed within the literature are a wake-up call for the need for adaptation on the part of universities in relation to the services offered to students with chronic illnesses in order to truly support them in a way that suits them (12).

Through this study we aimed to identify whether there are differences in the quality of life of students with chronic illness compared to students without significant health difficulties and to see the extent to which academic stressors predict quality of life for both students with chronic illness and those without significant health difficulties.

MATERIALS AND METHODS

The data was collected between May and July 2023, and the invitation was sent to students at three universities in the North-East region of Romania. The study received ethical approval from the ethics committee of the Faculty of Psychology and Educational Sciences in Iasi (number 595/12.05.2023).

Participants

A total of 260 students participated in this study and completed the questionnaires through an online survey platform (Google Forms). Of these, 3 people were excluded due to the fact that 2 had a chronic emotional illness and the other did not wish to declare a diagnosis of somatic illness. Of the remaining 257 participants, 52 had a diagnosis of chronic illness and 202 declared themselves clinically healthy. The mean age of the participants was 27.82 ± 9.09. Of the participants 33 were male and 224 females. In terms of education, 139 were pursuing a bachelor's degree, while 118 were pursuing a master's degree. Regarding the background, 67 were from rural areas and 190 from urban areas. In terms of residence, 47 lived in a dormitory, 2 in a host family, 82 rented, 37 with parents and 89 in their own home. The majority, 104, said they were in a relationship, 67 married and 86 singles. Of the total of 257, 15.6%

were following a doctor- prescribed treatment, 2.7% were self-medicating and 81.7 were not following any treatment. Chronic diagnoses included chronic renal failure, hypothyroidism, psoriasis, obesity, autoimmune thyroid, epilepsy, multiple sclerosis, asthma, etc.

Instruments

The first part of the assessment instrument aimed at collecting demographic data: university, faculty, educational cycle, year of study, gender, age, background, marital status, form of residence, health status, diagnosis of chronic disease, treatment. The second part included several questionnaires:

The World Health Organization Quality of Life-BREF (WHOQOL- BREF) (3) is a self-assessment tool for quality of life that can be applied to both people with and without a chronic illness. The 26 questions assess people's perceptions of four domains: physical health (Cronbach's $\alpha = 0.81$), psychological health (Cronbach's $\alpha = 0.86$), social relationships (Cronbach's $\alpha = 0.73$) and environment (Cronbach's $\alpha = 0.79$).

Academic Stress Scale (13) assesses through 18 items the level of stress felt by students in relation to the following four dimensions: pressures to perform (Cronbach's $\alpha = 0.59$), perceptions of workload and examinations (Cronbach's $\alpha = 0.61$), self-perceptions (Cronbach's $\alpha = 0.77$) and time restraints (Cronbach's $\alpha = 0.57$).

Statistical analyses

The variables of the present research do not differ statistically semi-significantly from a normal distribution, as the absolute value of the skewness coefficient is not greater than 1 (Labăr, 2008). Differences in quality of life dimensions according to the presence or absence of chronic disease were tested using t-tests for independent samples. To identify which stressors are significant predictors of quality of life according to the presence or absence of chronic illness, we used linear regression with the split file function activated.

RESULTS

Analyzing the first table we can see that there are significant differences according to the presence or absence of chronic disease in psychological health [$t(255) = -2.569$, $p = 0.011$], physiological health [$t(255) = -5.502$, $p < 0.01$] and social relationships [$t(255) = -2.640$, $p = 0.009$], but not in environment [$t(255) = -1.937$, $p = 0.054$]. Thus, students without a chronic disease have a better quality of life in the dimensions: psychological health, where they have a mean equal to 21.85, compared to students with a chronic disease who have a mean of 19.91; physiological health where they have a mean equal to 26.18, compared to the mean of 21.84 obtained by those with a chronic disease; and social relationships, where they have a mean of 11.12, compared to the mean of 10.02 obtained by students with a chronic disease (tab. I).

When the correlations between quality of life and academic stressors are analyzed among subjects diagnosed with a chronic illness, we observe that all correlations are significant and negative (tab. II), as follows: for the predictor pressure to perform ($r=-.45$, $p<.01$), for workload perceptions ($r=-.39$, $p<.01$), self-perceptions ($r=-.55$, $p<.01$) and for time limits ($r=-.50$, $p<.01$). Among people without a chronic illness, quality of life correlates negatively with pressure to perform ($r=-.46$, $p<.01$), workload perceptions ($r=-.33$, $p<.01$), self-perceptions ($r=-.56$, $p<.01$) and time limits ($r=-.42$, $p<.01$).

TABLE I.
T-tests for independent samples

Quality of life dimensions	Chronic disease	n	M	SD	t	df	Mr

	Absent		11.12	2.66			
Environment	Present		25.04	4.91	-1.937	255	0.054
	Absent		26.45	4.76			

TABLE II.
Correlations between predictors and criterion

Chronic disease		Quality of life	The pressure to perform	Perceptions work volume	Self-perceptions	Time limits
Present	Quality of life	1				
	The pressure to perform	-.458**	1			
	Perceptions work volume	-.397**	.653**	1		
	Self-perceptions	-.555**	.484**	.337*	1	
	Time limits	-.501**	.423**	.680**	.460**	1
Absent	Quality of life	1				
	The pressure to perform	-.463**	1			
	Perceptions work volume	-.334**	.583**	1		
	Self-perceptions	-.562**	.477**	.318**	1	
	Time limits	-.423**	.554**	.597**	.437**	1

*. Correlation is significant at the 0.05 level (2-tailed).
**. Correlation is significant at the 0.01 level (2-tailed).

Among subjects with a chronic disease, two significant predictive models were identified (tab. III), the first is made up of the self-perceived predictor ($F(1, 54)=23.62$, $p<.01$), and the second one from the predictors self-perceptions and time limits ($F(2, 54)=16.27$ $p<.01$), the model with the highest predictive power being the second one ($R^2 =.36$). The inclusion of the predictor time limits brings an additional information (Change $R^2 =.07$) statistically significant (Change $F(1, 52)=6.47$, $p=.01$). Thus, model 2 explains 36.1% of the variance of the quality of life variable, 7.7% more than model 1, this increase being statistically significant ($p =.01$). Within model 2, the predictor with the highest influence on the criterion is self-perceptions ($\beta=-.41$), followed by time limits ($\beta=-.31$). The effect of significant predictors is negative, when their score increases by one unit, the quality of life score decreases by -2.03 points for self-perceptions and by -1.33 points for time

limits (tab. IV).

In contrast, among subjects without chronic disease, three statistically significant predictive patterns were identified (tab. III). The first consists of the variable self-perceptions (F(1, 201)=92.13, p<.01), the second of the predictors self-perceptions and pressure to perform (F(2, 201)=57.16, p<.01), while the third consists of self-perceptions, pressure to perform and time limits (F(3, 201)=40.00, p<.01). The model with the highest predictive power is model 3, which explains 36.8% of the variance of the quality of life criterion, 1.2% more than model 2, the increase being statistically significant (p = .04).

TABLE III.

		Time limits	-1.330	.523	**-.312**	-2.545	**.014**	.788	1.269
Absent	1	(Constant)	107.858	2.480		43.497	.000		
		Self-perceptions	-2.705	.282	**-.562**	-9.599	**.000**	1.000	1.000
	2	(Constant)	116.423	3.234		35.996	.000		
		Self-perceptions	-2.124	.310	**-.441**	-6.862	**.000**	.773	1.294
		The pressure to perform	-1.045	.265	**-.253**	-3.939	**.000**	.773	1.294
	3	(Constant)	119.728	3.614		33.130	.000		
		Self-perceptions	-1.976	.316	**-.410**	-6.250	**.000**	.730	1.370
		Time limits	-.601	.302	**-.138**	-1.992	**.048**	.654	1.528
		The pressure to perform	-.789	.293	**-.191**	-2.695	**.008**	.625	1.601

In Model 3, the predictor with the highest influence on the criterion is self-perceptions (β=- .41), followed by pressure to perform (β=-.19), and the last predictor is time limits (β=-.13). The effect of significant predictors is negative, when their score increases by one unit, the quality of life score decreases by -1.97 points for self-perceptions, by -.78 for pressure to perform and by - .60 points for time limits (tab. IV).

DISCUSSION

The present study had two main objectives, namely to identify differences between the quality of life of students with chronic illness compared to students without significant health difficulties and to identify significant predictors of academic stressors. The results obtained agree with the literature, with students without chronic illnesses having significantly better quality of life than students with chronic illnesses on the dimensions of physical health, psychological health and social relationships. The only dimension for which differences were not significant was environment.

Due to the effects of chronic diseases on the body, such as pain, discomfort, the fact that the extent of physical health is more affected in chronically diagnosed students than in healthy students is not surprising (14). However, it is possible that students with chronic illnesses may have lower scores on the psychological dimension of quality of life as a result of the sensitivity exhibited by the body and psyche to the demands of the educational environment (15). Overall, the literature highlights that levels of happiness and subjective well-being in students with chronic illnesses are lower than in other students, partly due to lower levels of satisfaction of autonomy and competence needs (16).

According to our results, chronic illness can also have different effects on romantic relationships, or friendship, on the extent of relationships with others in general. Sometimes, especially when romantic partners have academic or professional responsibilities, the effects are irreparable, with relationships failing to withstand the impact of illness or treatment (17). In terms of friendships, often close friendships prior to illness drift away, or even disappear, while people known during treatment become close (17).

In terms of academic stressors, they all correlate negatively with quality of life. Among students with chronic illnesses, self-perceptions and time constraints were identified as significant predictors, while for students without chronic illnesses a significant predictor was also pressure to perform. It appears that the quality of life of students without chronic illnesses is negatively impacted, in addition to perceptions of self-confidence to succeed academically and professionally, by time limits for completing various tasks and by stress caused by parental expectations, competition with peers and criticism from teachers. The latter stressor is not a significant one for students with chronic illnesses and does not impact on their quality of life.

The present study has a number of limitations, the most important of which is the small number of subjects diagnosed with a chronic disease as opposed to healthy participants. Also, quality of life needs to be related to other variables besides academic stressors, such as coping strategies, or support from others. Future studies could also investigate whether the list of differences in environmental dimension is a reproducible result and what the possible explanations are.

CONCLUSIONS

One of the most important findings is that the quality of life of students with

chronic illnesses is significantly lower compared to students without chronic illnesses for the dimensions of physical health, psychological health and relationships with others. In addition to the fact that students' quality of life is impacted by academic stress driven by self-perceptions and time limits, that of students without chronic illnesses is additionally impacted by pressure to perform.

POSTMORTEM MACROSCOPIC DIAGNOSIS IN HYPOTHERMIA (Abstract): Accidental hypothermia fatalities are the result of extreme external environmental temperature exposure. These are an area of interest for research due to their complex features of diagnosis of certainty and the mechanisms involved in thanatogenesis. Our study aims to evaluate the macroscopic features associated with cold stress in a large group of accidental hypothermia fatalities. **Materials and methods:** The study comprised a retrospective analysis of 107 accidental hypothermia fatalities, diagnosed between 2007 and 2021, in the Forensic Medicine Institute Iași. **Results:** Variable reddish to purplish color cadaveric lividity, scrotum retraction (60% of males), intense red blood color (60.7% of cases), and skin lesions secondary to cold exposure, such as cold erythema or acute pernio (49.05% of cases), frostbites (49.7% of cases), and immersion foot (12.1% of cases) were the main macroscopic findings registered during autopsy. In addition, fetal position of the body and paradoxical undressing were other autopsy gross features identified in 12.1% and 9.3% of cases, respectively. The gross exam of the internal organs revealed Wischnewski spots (44.8%), pulmonary subpleural petechiae (11%), and Puharevici's sign (53.3%). Statistical analysis revealed a significant correlation between frostbites degree and temperature at hospitalization, between Wischnewski spots and core temperature, or alcoholaemia and traumatic injuries. **Conclusions:** Although the macroscopic features related to accidental hypothermia death are often non-specific, inconstant or even negative, their interpretation in the context of forensic investigation data, such as cold exposure evidence, social conditions, and histopathological data may contribute to hypothermia death diagnosis. **Keywords:** HYPOTERMIA, POSTMORTEM DIAGNOSIS, MACROSCOPY.

Hypothermia is the result of external thermal aggression, secondary to exposure to low temperatures (1, 2). This is defined by a state in which the body's temperature regulation mechanism is overcome by a stress factor, represented by an important decrease of environmental temperature, which settles at a core temperature below 35°C, at approximately 2°C below normal temperature (1). The loss of body heat, from the perspective of external and internal factors, is the result of the difference between the metabolic rate of the sum between physical exercise and the physical

parameters of temperature decrease (radiation, convection, and conduction) (3, 4).

Accidental hypothermia is a cause of death in at least 1,500 persons/year in the United States, while it ranges between 0.13 to 6.9 cases/100,000/ year in European countries and New Zealand (5).

Socioeconomic status, environmental factors, associated comorbidities, or alcohol and drug consumption are other factors that support hypothermia-related deaths (1, 5, 6). Depending on severity, hypothermia is divided into mild hypothermia (35-32°C core temperature), moderate hypothermia (<32-28°C core temperature), severe hypothermia (<28°C core temperature), and profound hypothermia (<24°C core temperature) (7). In the mild form, the patient shows obnubilation, lack of movements coordination, dysarthria, myosis, cold and pale teguments (8). In the moderate form of hypothermia, associated with death in approximately 20% of cases, the altered state of consciousness sets in, the teguments become cold, added to bradypnea, bradycardia, hypotension, and the occurrence of Osbourne J wave, while the cold sensation disappears (8). In progression, ventricular fibrillation, disseminated intravascular coagulation, hyperkalemia, acidosis, and coma occur in severe form of hypothermia, leading to a mortality rate >50% (8).

Death by hypothermia is associated with a series of frequent non-specific macroscopic and microscopic changes, which may lead to difficulty in diagnosis, in medico-legal practice (5, 9).

A fetal body position may be adopted by victims of hypothermia, but it may be absent in cases of alcohol consumption, or paradoxical undressing may be encountered, due to the hypothalamus failure of body temperature control or to the peripheral vasodilation and false perception of heat sensation (1, 9). These are associated with a series of external and internal macroscopic changes identified during the medico-legal necropsy, such as cadaveric lividity, skin lesions induced by prolonged exposure to cold (joints cold erythema), scrotal retraction, along with cardiac, gastric, pancreatic, renal, and/or muscular hemorrhages (1, 9, 10).

Although indicative in nature, macroscopic changes, corroborated with forensic investigation data and the results of the microscopic histopathological examination, may direct the diagnosis towards death by hypothermia in medico-legal practice (11).

In this context, the purpose of the present study is to investigate the macroscopic changes noted during the necropsy examination in a group of hypothermia victims, as well as the correlation between these changes and epidemiological and biochemical data.

MATERIALS AND METHODS

The medico-legal files of 107 cases having hypothermia circumstances of death, registered between 2007-2021, from the archive of the Institute of Forensic Medicine Iași, were re-examined and included in our study group. In all cases, 10 mL blood samples were collected from the femoral vein to determine the ethanol concentration. Additionally, 50 mL urine sample was collected to determine the alcoholuria.

The macroscopic lesions identified in these patients were statistically investigated by IBM SPSS v.26 program, using Mann Whitney and Spearman tests. p value <0.05 was considered as statistically significant.

Our study had the approval of the Research Ethics Committee of "Grigore T.

Popa" University of Medicine and Pharmacy, Iasi, no. 17275/20 August 2019, consistent with the Declaration of Helsinki - Ethical Principles for Medical Research Involving Human Subjects.

RESULTS

Among the total number of 107 cases of death by hypothermia analyzed in our study, 81 cases (76%) were male and 26 (24%) were female, the average age being 57.95±1.47 years. Most cases (68.2%) inhabited in rural areas and only 31.8% of cases inhabited in urban areas. Low socioeconomic status was registered in 18.7% of women victims, while alcoholism and severe meteorological conditions represented the predisposing factors of hypothermia in men, in 24.3% and 9% of cases, respectively (fig.1). Additionally, the death occurred at domicile in 10.3% of women and in hospital in 22.4% of men, respectively (fig. 2).

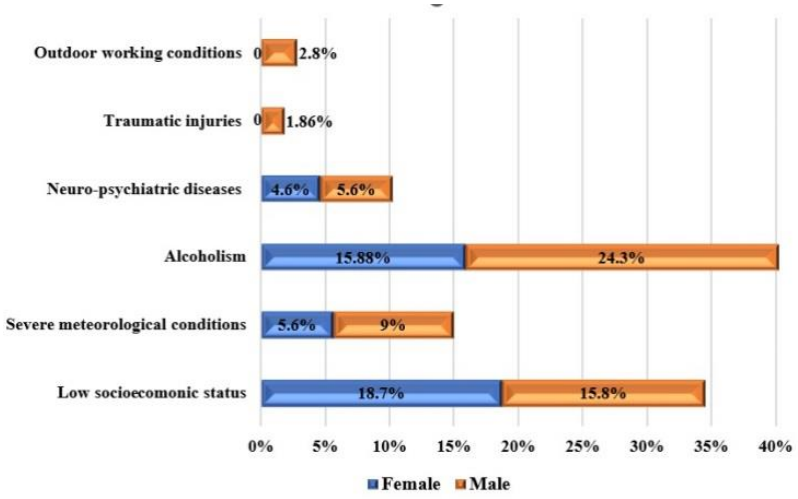

Fig. 1. Distribution of factors contributing to death by hypothermia according to gender

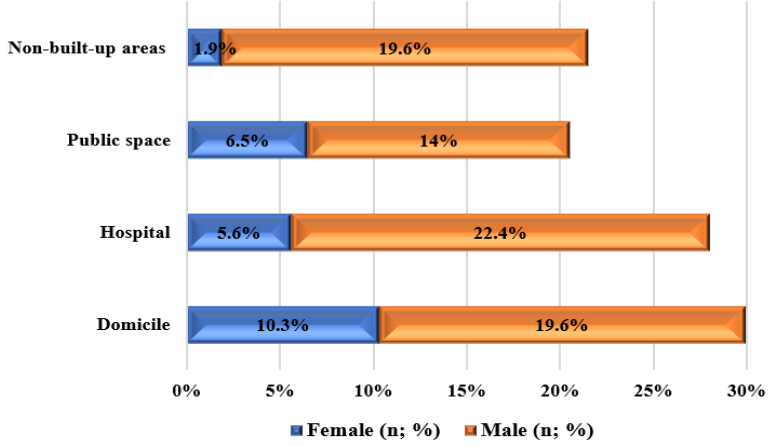

Fig. 2. Distribution of cases in relation to place of death according to gender

External exam

90.6% of cases included in the study group were found fully clothed and the phenomenon of paradoxical undressing was registered only in 9.3% of cases. 30% of cases presented a variable hospitalization period (from 1 to 30 days), the temperature at hospital admission varying between 19.5°C and 32.6°C. In these cases, death occurred due to cardio-respiratory complications (25.6%) or multiple organ failure (MOF) (25.6%). Three cases (2.8%), all men, were found frozen.

The external examination also revealed retraction of the scrotum (Puparev's sign) in 60% of men, while the other signs detected were: fetal position in 12.1% of cases, intense reddish cadaveric lividity in 31.1% of cases, cold erythema in 49.05% of cases, predominantly detected in the lower limbs (34.15%), different degrees of frostbites in 49.7% of cases, classified from first up to fourth degree, according to their severity, and immersion foot in 12.1% of cases, with variable rates among the victims genders (figs. 3-9).

Fig. 6. Immersion foot in a case of hypothermia

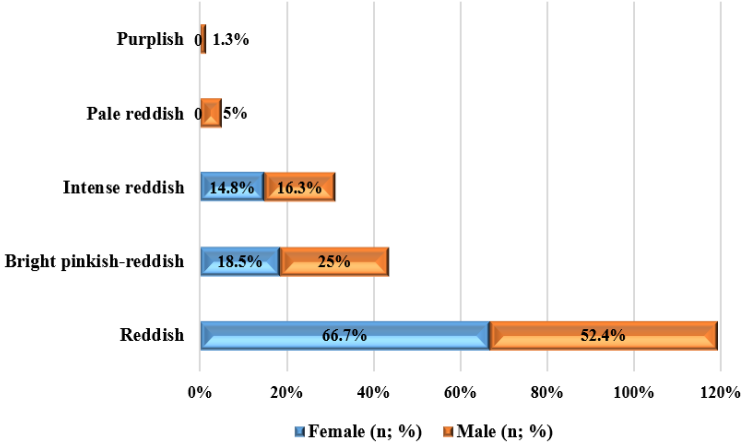

Fig. 7. Distribution of cadaveric

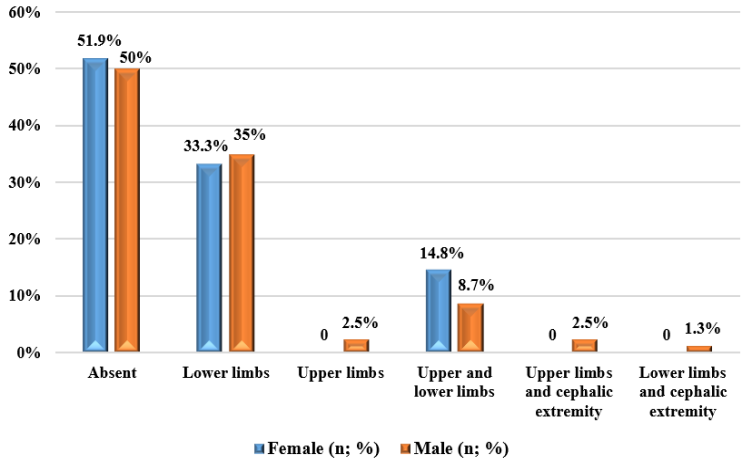

Fig. 8. Distribution of cold erythema according to gender

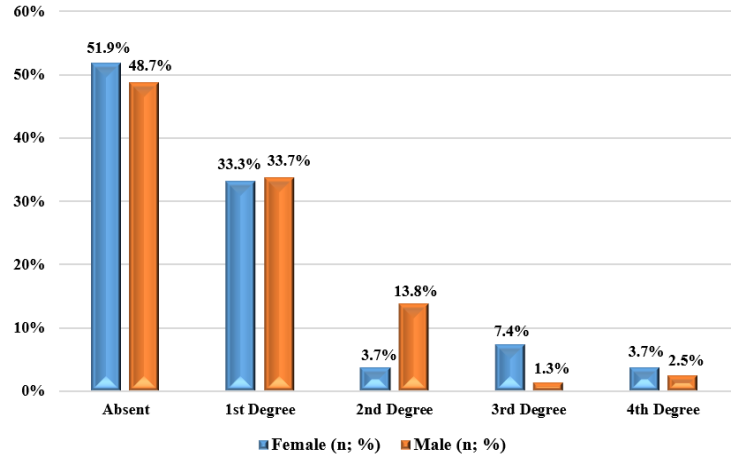

Fig. 9. Frostbite degree according to gender

In addition, Spearman's test indicated a significant correlation ($p<0.05$) between the frostbite degree and the temperature at hospitalization, with a higher degree corresponding to the lowest temperatures.

Internal exam

The internal examination of the corpses also revealed a series of injuries of the internal organs secondary to exposure of the body to low temperatures, such as gastric hemorrhagic erosions (Wischnewski spots) in 44.8% of cases, stomach retraction (Puharevici's sign) in 53.3% of cases, pulmonary subpleural petechiae in 11% of cases (figs. 10 and 11), pancreatic hemorrhages in 18.7% of cases, and intense reddish blood color in 60.7% of cases. Macroscopically identified Wischnewski spots, partially confirmed by histopathological examination, were correlated with a more

pronounced drop in body temperature (mean value of 22.42°C).

Simon's hemorrhages (of the anterior aspect of the lumbar intervertebral discs) and hemorrhages of the major psoas muscle or of the paravertebral muscles were not highlighted in order to preserve the body integrity as much as possible, if other signs of hypothermia have been noticed.

Fabrikantov spots (hemorrhagic areas in renal pelvis) were absent in 99.1% of cases, and no information was available for 1 case, as postmortem hemicorporectomy was registered.

Independent samples T-test revealed significant differences between cases with Wischnevski spots and those without it, in terms of temperature at hospitalization. Thus, cases diagnosed with Wischnevski spots had a significantly body lower temperature (mean temperature 24.15±2.79°C) compared to cases without this sign (mean temperature 26.17±2.91°C).

The internal examination also revealed the presence of pulmonary edema in 54.9% and bronchopneumonia in 17.6% of cases. Steatosis, diagnosed in 71.4% of cases, along with liver cirrhosis (6.5% of cases) and pancreatic hemorrhagic lesions (6.5% of cases) were among the most common macroscopic lesions noted in the digestive tract and its accessory organs.

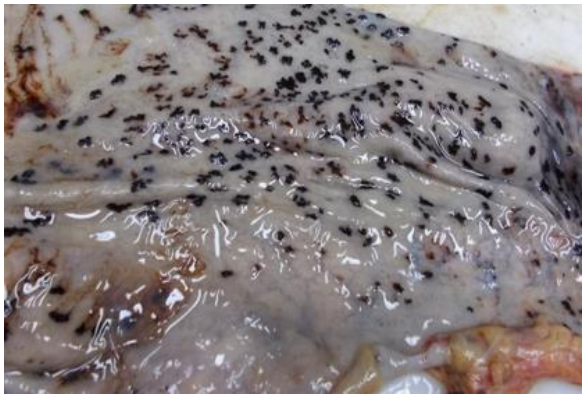

Fig. 10. Stomach Wischnewski spots in a case of hypothermia

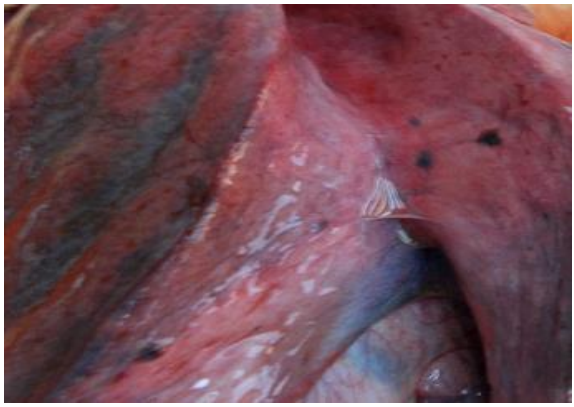

Fig. 11. Subpleural petechiae in a case of hypothermia

Alcoholaemia was positive in 42% of cases, with a range between 0-4.65g/L, its higher values being noted in men, while alcoholuria was positive in 24.3% of cases.

Traumatic injuries have been registered in 72 cases (67.3%), 62 cases (86.1%) of them having passive lesions, while 10 cases (13.9%) having non-fatal assault lesions.

The non-parametrical Mann Whitney test showed that the alcohol level was significantly higher in cases with injuries of violence produced by active force, followed by same-level falls (MR = 41.65), compared to cases with injuries produced by passive trauma (falls) (MR = 29.55) [U = 158,500; p = 0.036]. Additionally, the data showed that alcoholuria was significantly higher in cases with injuries produced by active impact followed by same-level fall (MR = 31.33) compared to cases with injuries produced by passive impact (fall) (MR = 19.53) [U = 69,000; p = 0.006] and for cases with injuries produced by active force followed by same-level fall (MR = 18.17) compared to cases without injuries (MR = 11.92) [U = 43,500; p = 0.041].

Regarding complications during hospitalization, most cases had neurological complications (46.2%), followed by MOF (25.6%), and cardio-respiratory complications (25.6%). Regarding the neurological complications of the encephalopathy type, we identified the following subtypes: post-anoxic encephalopathy (6 cases), ethanolic encephalopathy (1 case), toxic-ethanolic encephalopathy - polyneuropathy (1 case).

Following the application of the non-parametric Mann Whitney test to verify significant differences, it was found that the temperature at admission was significantly lower for MOF complications (MR = 5.72) compared to cases with cardio-respiratory complications (MR = 10.70) [U = 6,500; p = 0.032] and for neurological complications (MR = 10.44) versus cases with cardio-respiratory complications (MR = 17.60) [U = 17,000; p = 0.037], where MR represents the mean of the ranks and U represents the Mann Whitney Test.

DISCUSSION

The diagnosis of death by hypothermia is achieved by correlation of the autopsy data with the forensic investigation data on the spot and with the histopathological exam, by excluding some alternative causes of death and analyzing the circumstantial records, without means of estimation of the severity of ante-mortem cold exposure (11). The macroscopic data resulting from the external and internal examination of the corpse can provide important information, which points towards the diagnosis of death by hypothermia in medico-legal practice.

Cold erythemas and frostbites, mainly located on the extremities (earlobes, fingers and toes, or nose tip) or unclothed skin surfaces are the main skin lesions noted in hypothermia victims (12), in agreement with our findings. These become permanent changes if the freezing process is leading to cellular water crystallization in an extensive manner (12). Moreover, frostbitten skin areas must be surgically removed in people who survive low temperatures exposure, as they are territories devoid of vitality (13). Moreover, first-degree frostbites were mainly registered in our study, being detected in more than a third of cases of both genders in our study group.

Immersion foot sign is commonly related to prolonged exposure to moisture and classically occurs after more than 12 hours of cold-water exposure, in hypothermia fatalities (14). Sudden immersion in cold water may lead to skin's rapid cooling,

followed by uncontrollable hyperventilation and a concurrent rise in cardiac output and blood pressure, precipitating pre-existing cardiovascular pathology in susceptible individuals. The lack of cold-water habituation, advanced age, and pre-existent cardiovascular pathology were the most significant factors that led to a fatal end in a victim diagnosed with immersion foot, in our study group (14, 15).

The cadaveric lividity is represented by pink/bright red postmortem coloring of the teguments on their sloping sides due to the antemortem binding of oxygen to hemoglobin and its postmortem diffusion through the skin (16, 17). These observations are also supported by the results of our study, as the tints of lividity color were mainly intense in the investigated cases.

Core cooling of the body occurs regardless of the position adopted, but studies show that the decrease of core temperature occurs faster in the upright position (by approximately $1.24^{o}C \pm 0.07^{o}C$) than in the supine position (by approximately $1.02^{o}C \pm 0.06^{o}C$), including a significantly lower thermogenesis threshold temperature in the upright position compared to the recumbent position (18). In our study, we observed that victims found in the prone position managed to survive long enough to be admitted to the hospital, where rewarming and resuscitation was attempted, with a mean admission temperature of $25.58^{o}C$.

Regarding the blood color, the victims included in the study group presented an intense reddish coloration (60.7%), our data agreeing with other literature reports (1, 16).

Retraction of the scrotum and testicles was observed in 60% of the male cases, the Puparev's sign being present in 35.5% of the cases that did not survive long enough to be hospitalized. These findings are also supported by the literature mentioning that the Puparev's sign (wrinkled scrotum with testicles lifting in the direction of inguinal canals) occurs with a frequency of 38% and is part of the category of the first signs that appear in the setting of hypothermia along with cutis anserine (goose bumps), Shter's sign (pose of shivering person), cold erythema, Rayski's sign (frost of the eyelashes, with icicles in the openings of the nose and mouth), and Puharevici's sign (an empty stomach with folded mucous membrane covered with vitreous mucus) (1, 19, 20).

Wischnewski spots are hemorrhagic lesions as areas of 1mm-2cm diameter, black-brown in color, dispersed on the surface of the gastric mucosa, but without a pathognomonic value for hypothermia diagnosis (21, 22). According to literature data, these are observed in hypothermia victims in a range between 40-100% (9, 21, 22). Similar data were obtained in our own research, as the identification of Wischnewski spots was registered in 48 cases (44.8%) of our study group, although our observations could lead to underdiagnosis considering the marked postmortem autolysis, which did not allow a conclusive macroscopic interpretation of the stomach surface. Wischnewski spots identification during the autopsy guided the coroner to the death cause, especially in circumstances where the investigation data were inconclusive or insufficient.

Fabrikantov spots, as hemorrhagic areas due to kidney hypoxia have been identified only in 0.9% of cases in our research. The registered differences by comparison with a report of positive Fabrikantov spots in 75.1% of a group 460 victims of hypothermia (23) may be attributed to marked autolysis and putrefaction or to the therapy

applied during hospitalization.

Regarding macroscopic pancreatic hemorrhages and pancreatitis signs, these have been observed in 20 cases (18.7%) in our study, data consistent with those of a report with 5 cases (3.49%) in a study conducted on 143 victims, being correlated with time of cold exposure (24).

A severe form of hypothermia that can lead to death is that resulting from exposure to low temperatures in association with the consumption of ethanol, since alcohol acts as a strong peripheral vasodilator and a central anesthetic. These effects lead to a supplementary heat loss that is not counterbalanced by a corresponding increase of thermogenesis (3, 5, 25). Additionally, by increasing the blood flow to the skin and extremities, alcohol induces a false warmth sensation, while heat loss increases. The ethanol consumers may have a higher rate of hetero-aggressive behavior, which in combination with toxicological and traumatic factors, and may influence the exposure of victims to extreme temperatures, either due to the loss of consciousness or the inability to leave the cold environment. Moreover, according to the results published in the international data flow, a variable percentage, between 33% and 73% of hypothermia cases, are complicated by the consumption of ethanol (6, 10, 16). In this sense, it is already recognized that people who fall asleep under the action of ethanol, while being hypothermic, will succumb due to extreme hypothermia.

This study had some limitations given by the difficulty in discrimination between pre-existing macroscopic lesions and non-specific injuries induced by hypothermia, the incomplete information regarding the circumstances of death and time of cold stress exposure, along with the difficulties of external and internal lesions evaluation during autopsy exam in the context of postmortem autolysis.

CONCLUSIONS

The forensic specialists play an important role in the establishment of the death diagnosis by hypothermia, following the corroboration of the forensic information resulting from the on-site investigation and the witnesses' inquest, the information during the necropsy (external and internal examination of the body), the toxicological information, requiring final histopathological confirmation.

While, in most cases, due to the short survival time in the hostile temperature conditions, there is a lack of macroscopic features that could suggest or guide the cause of death to hypothermia, the internal body examination may provide important clues for diagnosis. Following frostbite erythema observed in external exam, Wischnewski spots, detected by internal examination, have the greatest practical value in establishment of the diagnosis of death by hypothermia.

The intensity of the macroscopic changes of the internal organs depends on the difference between the victim's body temperature and the ambient or the water temperature (in case of immersion) and the period of cold exposure, so the absence of macroscopic lesions can be justified by a short interval of time to death by a sudden drop in body temperature, making the postmortem diagnosis of hypothermia death difficult, especially if there is no suspicion and appropriate circumstances.

CONFLICT OF INTEREST

The authors declare that there is no conflict of interest.

METFORMIN'S IMPACT ON SERUM IMUNOGLOBULINS AND BRONCHOALVEOLAR LAVAGE CELLS IN MICE WITH COMPLICATED SEVERE ASTHMA (Abstract): **Background:** Severe asthma represents an important burden of mortality and morbidity in asthma being a clinical condition that has the risk of evolution to acute lung injury (ALI). Based on the anti-inflammatory and airway anti-remodeling effect of Metformin we presumed that it will promote beneficial effects in severe asthma complicated to ALI. Our study aimed to evaluate the effects of Metformin on a murine model of severe asthma complicated with ALI by assessing the modulatory effect of Metformin of plasma IgE levels and on differential cell count from bronchoalveolar lavage fluid. **Materials and methods**: There were three groups of BALB/c mice with ovalbumin (OVA)-induced asthma followed by ALI induction which consisted in OVA sensitization (days 0 and 7) and challenge (days 14, 15, 16 and 17) followed by lipopolysaccharide (LPS) intratracheal instillations (days 15 and 17) treated 30 min before OVA, in days 14-17: positive control group for disease (OVA+LPS), Dexamethasone treatment group (DEXA + OVA + LPS) and Metformin treatment group (OVA + LPS + METF). Measurement of OVA-specific IgE levels was made and bronchoalveolar lavage fluid (BALF) was collected in order to apply differential cell count. **Results**: administration of Metformin decreased the airway macrophage infiltration with no modulatory effect on airway neutrophilic infiltration. **Conclusions**: Metformin has the potential to influence the physio-pathological changes that occur in asthma followed by ALI. However, new studies to explore the specific mechanism by which Metformin influences the inflammatory and immune response in asthma/ALI overlap are needed. **Keywords**: METFORMIN, SEVERE ASTHMA, ACUTE LUNG INJURY, LIPOPOLY-SACCHARIDE.

INTRODUCTION

Asthma is a respiratory disease characterized by airway chronic inflammation and remodeling. It has a high prevalence being estimated that 334 million people worldwide are suffering from asthma (1). Severe asthma proposes a significant challenge in clinical practice considered to affect a small proportion of asthmatic patients but accounts for a significant burden of morbidity and mortality correlated with asthma (2). Available data show that severe asthma is involved in increasing the risk of pneumonia which is the most common cause for acute lung injury. Therefore, asthma is a condition that influences the risk of progression to acute lung injury (3, 4).

Acute lung injury (ALI) consists in a common respiratory disease defined by acute lung inflammation having as main pathological characteristics inflammatory cell infiltration and high permeability pulmonary edema (5). Although the therapeutic strategies of this disease are complex, the mortality and morbidity levels are high (6).

Metformin (METF), a drug used as first line agent in diabetes type 2 (7). Recent studies have highlighted its pleiotropic pharmacodynamic profile (8) and its beneficial involvement in both bronchial asthma and ALI based mainly on its anti-inflammatory and airway anti-remodeling effect (9-11).

The aim of our study was to evaluate the effects of Metformin on a murine model of severe asthma complicated with ALI by determining IgE plasmatic concentrations and evaluating the differential cell count from bronchoalveolar fluid (BALF).

MATERIAL AND METHODS

Study Design

The experiment was carried on 18 mice (females BALB/c, weighing 17-23g) from "Cantacuzino" Institute in Bucharest. Experimental site was in CEMEX facility of "Grigore T. Popa" University of Medicine and Pharmacy of Iasi, under normal conditions of temperature (22±3°C), humidity (55±5%), 12 hours day/night cycles of and with water and food *ad libitum*. Ethical approval (No. 335/17.07.2023) was obtained from The Research Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy of Iași, Romania.

Animals, divided into 3 groups of 6 animals each, were treated intraperitoneally, once a day, as follows: OVA+LPS group (positive control for disease) with saline solution (0.5 ml/mouse); OVA+LPS+DEXA group (DEXA group; positive control for treatment) with Dexamethasone (1 mg/kg); OVA+LPS+METFgroup (Metformin group) with Metformin (250 mg/kg).

Induction of severe allergic asthma and lung inflammation was realized with OVA(GRADE V, Sigma-Aldrich, St. Louis, MO, USA), through sensitization procedure on days 0 and 7 through intraperitoneal once a day administration of 0.2 ml/mouse OVA/aluminium hydroxide solution(Sigma-Aldrich Chemie GmbH, Deutschland) (12),and followed by the challenge procedure on days 14, 15, 16, 17, with OVA 1% aerosols (10 ml/mouse) and lipopolysaccharide (LPS) (lipopolysaccharide from Escherichia coli 0127: B8, Sigma-Aldrich, St.Louis, MO, USA) intratracheal administration on days 15 and 17 (13).

Measurement of plasma IgE levels

Blood was collected by intracardiac puncture in 0.5ml microcentrifuge tubes and the serum was separated from whole blood

by centrifugation at 3.000 rpm at 4°C for 10 min and immediately frozen at −80°C. Total IgE levels were measured with enzyme-linked immunosorbent assay (ELISA) using OVA-specific IgE using a Legend Max Mouse OVA Specific IgE ELISA kit (Biolegend, USA). ELISA plates were read with an Infinite 200 PRO M Plex Tecan 314 plate reader (Tecan, Austria) and Magellan 7.4 software (Tecan, Austria).

Bronchoalveolar lavage fluid (BALF) and differential cell count

BALF collection was through an incision in the trachea which was exposed and then cannulated and began 24 hours following the last challenge with OVA, under ketamine and xylazine general anesthesia. The BALF collection process involved three successive infusions-aspirations of 0.5 ml warm (37°C) PBS through the tracheal cannula, totaling 1.5 ml. The fluid was kept on ice until centrifuged at 250 g for 5 min at 4˚C. The supernatants were collected and transferred to Eppendorf tubes, centrifuged at 10,000 g for 15 min at 4˚C, aliquoted as 150 µl samples into other tubes and stored at -80˚C until assessment of cytokines. Following vortex mixing, 5 µl of the residual cell pellet from the 250 g centrifugation were used to prepare slides that were next stained with May-Grünwald (Sigma-Aldrich, 1.01424, USA) and Giemsa (Sigma-Aldrich, 1.09204, USA). Using an optical microscope (Leica DM6 B, Germany) with a dry objective lens (40x), ten microscopic fields were examined to determine the mean cell count per field. Additionally, in order to differentiate neutrophils, eosinophils, lymphocytes, and macrophages, 200 cells were examined with an immersion objective lens (100x), using the same optical microscope.

Statistical Analysis

Data is presented as means ± standard error (SE). The statistical analysis was done using *SPSS* software. The assessment of statistically significant differences between groups was made using parametric tests (One-Way Analysis of Variance (ANOVA) followed by the Holm-Sidak method for multiple parametric comparisons), or nonparametric tests (Kruskal-Wallis One-Way ANOVA on ranks). P-values less than 0.05 were statistically significant.

RESULTS

Plasma Ig E levels

The serum levels of OVA-specific IgE were evaluated in all three groups. The highest plasma IgE levels were detected in DEXA group followed by the levels induced by Metformin administration, but without significant statistically differences between the treated groups and the positive control group for disease (Kruskal-Wallis One-way ANOVA on ranks: H = 3.500 with 2 degrees of freedom; p=0.174; ns).

Analysis of cell count in Bronchoalveolar Lavage Fluid (BALF)

Figure 1 shows the microscopic characteristics of inflammatory cells from BALF.

Intratracheal instillation of LPS resulted in a significant predominance of neutrophilic infiltration observed in the OVA+LPS group, confirming the potency of the ALI-induction experimental model. Treatment with Metformin did not alleviate the neutrophilic infiltration, without no significant statistical differences between the OVA + LPS + METF group and the

OVA+LPS group (p>0.05). The treatment with Dexamethasone did not exhibit an effect on the neutrophilic infiltration either, with no statistically significant differences noted between the DEXA group and the OVA+LPS group (p>0.05). Treatment with METF resulted in a decrease in the total number of macrophages compared to OVA + LPS group (p<0.05), but did not induce a significant statistical difference compared to DEXA group (p>0.05). Compared to OVA + LPS group the number of lymphocytes from DEXA group and METF group was not significant statistically different (One-way ANOVA: F(2,15) = 0.162 p = 0.852; ns). The assessment of eosinophils in BALF did not provide any significant statistical differences between groups (One-way ANOVA: F(2,15) = 0.678 p = 0.525; ns).

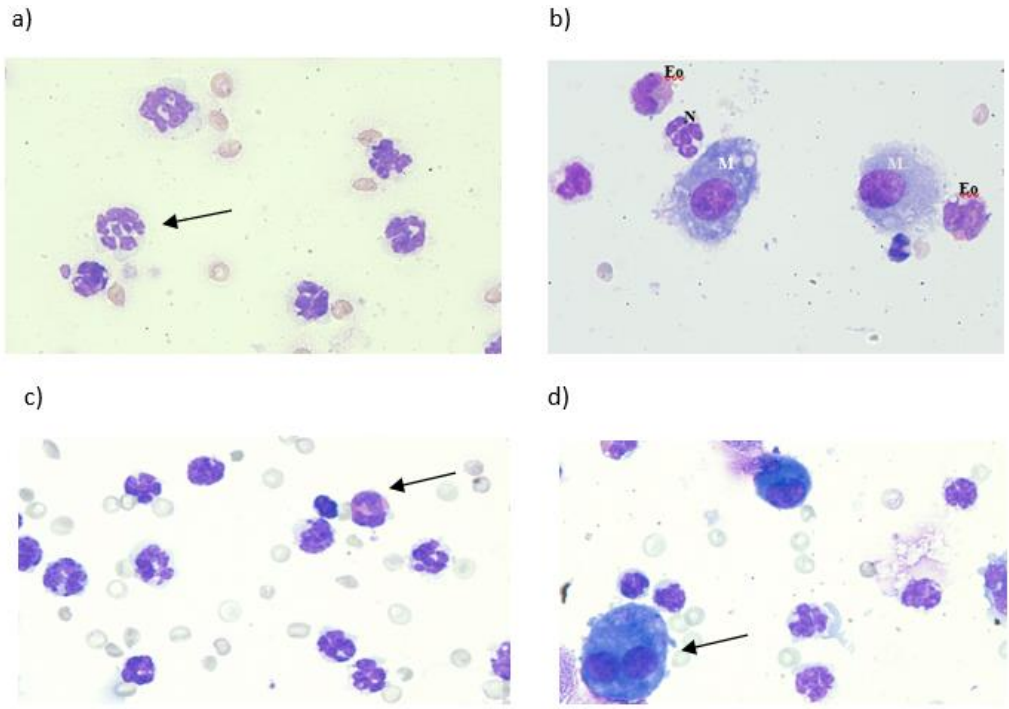

Fig. 1. Differential cell counts on optical microscopy, x100 immersion objective a) OVA + LPS group: neutrophils, hyper-segmented neutrophil (arrow); b) OVA + LPS +DEXA group: alveolar macrophages (M), neutrophils (N) and eosinophils (Eo); c) OVA + LPS +METF group: neutrophils and an eosinophil (arrow); d) OVA + LPS +METF group: neutrophils and two alveolar macrophages, one binucleated (arrow); OVA + LPS: positive control for disease; OVA + LPS + DEXA: Dexamethasone treated group; OVA + LPS + METF: Metformin treated group.

In each group, the differential number of cells represented by eosinophils, neutrophils, lymphocytes and macrophages was counted (fig. 2)

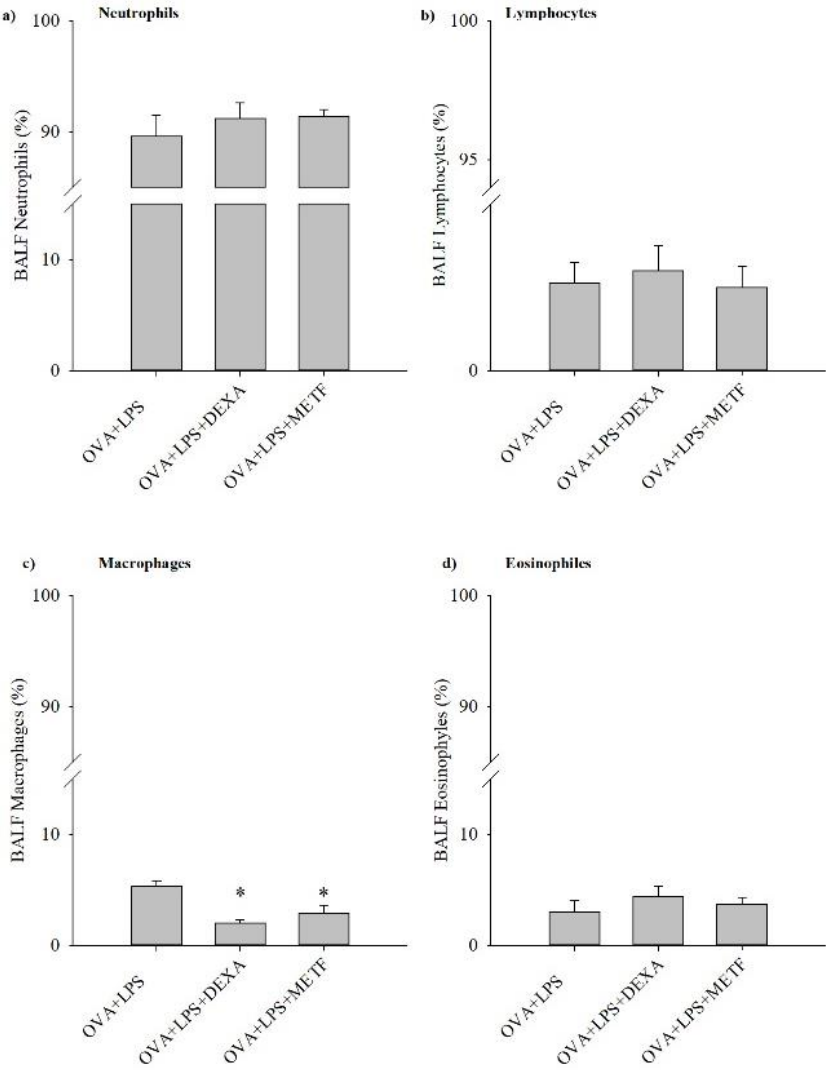

Fig. 2. Cell differential count in bronchoalveolar lavage fluid in percentages for (a) neutrophils; (b) lymphocytes; (c) macrophages; (d) eosinophils. Values are expressed as mean ± standard error; n=6. One-way ANOVA: * $p < 0.05$ *vs.* OVA+LPS group; followed by the Holm-Sidak method for multiple comparisons. OVA + LPS: positive control for disease; OVA + LPS + DEXA: Dexamethasone treated group; OVA + LPS + METF: Metformin treated group.

DISCUSSION

The results of our research highlighted the rich predominant neutrophilic airway infiltration which confirms the authenticity of the experimental model. It is considered that the neutrophilic airway infiltration

represents a defining feature of ALI which promotes epithelium and endothelium lesions through the release of cytotoxic molecules (14). Our study shows that the total neutrophils count induced by LPS was not influenced by the administration of Metformin nor by Dexamethasone. The results showing the eosinophilic and lymphocytes airway infiltration in all three experimental groups are sustaining the potency of the induced experimental model.

Data from literature shows the alleviating effect of Metformin on the airway neutrophilic infiltration in a mice model of ALI. The research published by Yu L *et al.*, points that Metformin is efficient in decreasing neutrophilic airway infiltration through inhibiting myeloperoxidase activity (15). Thus, our study presents contradictory results, this aspect could be interpreted in the context of the complexity of the animal model, being a severe asthma ALI overlap which leads to the idea of other possible underlying mechanisms of Metformin in this respiratory pathology. However, another study indicates that Metformin is efficiently in reducing neutrophilic infiltration in LPS-induced ALI in diabetic mice exposed to methylglyoxal MGO, being proposed the scavenger MGO activity of Metformin. The particular point of this study is that Metformin by itself in diabetic mice which were not exposed to MGO did not influence the neutrophilic infiltration induced by LPS (14).

Our statistical analyze on BALF cell count revealed that Metformin was efficient in decreasing the macrophage airway infiltration induced by LPS administration. Our results are confirmed by another study which points the effect of Metformin in reducing macrophage infiltration in an experimental model of ALI by suppressing LPS-induced endothelial cell pyroptosis mediated by SIRT-1 activation (16). Data show the essential role of macrophage in inflammatory respiratory diseases like allergic asthma, ALI and chronic obstructive pulmonary by initiating immunity and host defense (17, 18). In ALI the macrophages are involved in the modulation of the inflammatory response and also in the process of repairing damaged tissue (19). Based on the important role of macrophages in alveolar and lung environment the regulation process of macrophage function is proposed as therapeutic target in inflammatory respiratory disease (18).

Regarding the role of Metformin in modulating Ig E levels in respiratory diseases the published data show that Metformin has the ability to reduce OVA-specific Ig E in chronic asthma in mice (9). Our study consisting in severe asthma complicated with ALI revealed no modulatory effect of Metformin nor Dexamethasone on OVA-specific IgE levels.

Our research did not show significant differences between the potency of Metformin and Dexamethasone treatment. An interesting result is the rich neutrophilic infiltration in DEXA group. These findings can be approached based on the fact that in steroid resistant asthma phenotype Dexamethasone proven to have an impaired function in inhibiting IL-8 production which leads to persistent neutrophilic inflammation (20). Also, our results are consistent with another study that reveals that Dexamethasone treatment fails to reduce neutrophilic airway inflammation in a murine model of asthma (21).

The research direction of our study is valuable considering the clinical studies

which aim to explore the potential of Metformin treatment in reducing asthma exacerbations and acute lung severity in diabetic patients. The clinical data have controversial results, being shown the positive effect of Metformin treatment in reducing the risk of asthma exacerbation in diabetic patients (22), but also there are studies that reveal that Metformin treatment increased the risk of exacerbation asthma in diabetic patients (23).

CONCLUSIONS

Our research revealed the potency of Metformin in reducing the airway macrophage infiltration, a therapeutic target that could be influenced in severe asthma complicated with ALI. The results open the necessity of following experimental research in order to assess the therapeutic effect of Metformin in asthma-ALI overlap.

CONFLICT OF INTEREST AND FUNDING

The authors declare no conflict of interest.

CORRELATION BETWEEN BREAST ARTERIAL CALCIFICATIONS ON MAMMOGRAPHY, CHOLESTEROL LEVELS AND CARDIOVASCULAR RISK (Abstract): The **objective** of this study is to evaluate the correlation between arterial calcifications observed on mammograms and factors such as age, smoking status, body mass index, personal history of cardiovascular conditions, cholesterol levels (total cholesterol, LDL, HDL), and diabetes mellitus. **Materials and methods**: This retrospective study comprised a cohort of 1102 women, aged between 32 and 85, who underwent mammography at the "Sf. Spiridon" County Clinical Emergency Hospital Iasi from January 2018 to December 2020. Every woman underwent a routine procedure of bilateral four-view mammography. The patient's clinical and laboratory data were retrieved from the hospital's internal database. We selected in a random manner 115 age-matched women who did not have arterial calcifications in order to form the control group. **Results:** Out of the patients who received mammography, 95 cases (8.6%) showed the presence of breast arterial calcifications (BAC). As compared to control group, a significantly proportion of women with breast arterial calcifications were found to have a high body mass index (76.84%), elevated total cholesterol levels, cardiovascular diseases (21 cases, 22.10%), diabetes mellitus (15 cases, 15.78%), history of smoking (26 cases, 27.36%). **Conclusions**: The presence of breast arterial calcifications (BAC) on mammography is strongly linked to older age, elevated cholesterol levels, smoking, and diabetes mellitus. These patients also have a personal history of cardiovascular events, indicating a strong connection between BAC and an increased risk of cardiovascular problems. This correlation suggests that detecting BAC on mammography can serve as a marker for identifying women who are at a higher risk for experiencing cardiovascular events. **Keywords:** MAMMOGRAPHY, ARTERIAL CALCIFICATIONS, CARDIOVASCULAR RISK.

Mammography is a widely utilized imaging technique for detecting breast calcifications. During screening mammography, breast arterial calcification (BAC) is often detected. BAC refers to the benign and incidental medial calcification of the

mammary arteries. The formation of these calcifications is believed to occur through a complex process involving vascular inflammation, cellular damage, and subsequent mineralization of the arterial wall (1, 2, 3). It is becoming more and more evident that the presence of BAC during routine mammographic screenings could be a sign of increased risk for cardiovascular disease (CVD). Recent research indicates that the detection and severity of breast arterial calcifications can offer valuable insights into an individual's cardiovascular well-being and risk factors (4, 5). For instance, multiple studies have indicated a correlation between breast arterial calcifications and an increased risk of developing cardiovascular disease (6, 7, 8, 9).

Research on the relationship between breast arterial calcifications on mammography and systemic markers of cardiovascular risk, such as cholesterol levels, is gaining momentum. Studies have found a correlation between elevated cholesterol levels and a higher likelihood of developing breast arterial calcification. Previous studies have discovered a correlation between elevated total cholesterol levels in women and the presence of breast arterial calcifications on mammography. Furthermore, certain studies have found a connection between the existence of breast arterial calcifications and elevated triglyceride and low-density lipoprotein levels. It is evident that breast arterial calcifications can serve as a valuable indicator of the overall atherosclerotic process, giving clinicians an extra means of evaluating cardiovascular risk (10, 11, 12, 13).

In addition, the presence of breast arterial calcifications has been associated with a higher risk of cardiovascular events, including myocardial infarction, stroke, and cardiovascular death. It has been observed that patients with breast arterial calcifications tend to have a greater amount of coronary artery calcification and atherosclerosis, which in turn raises their chances of experiencing negative cardiovascular outcomes (14, 15, 16, 17, 18).

There is compelling evidence indicating a connection between breast arterial calcifications observed on mammography, cholesterol levels, and the potential for cardiovascular disease. Studies have shown that certain cardiovascular risk factors, including hypertension, smoking, and obesity, can potentially raise the risk of developing breast arterial calcifications (19, 20, 21). According to a systematic review conducted by Osman *et al.*, it was discovered that women with hypertension have a higher likelihood of having breast arterial calcifications on mammography compared to women without hypertension (22).

The existing evidence strongly indicates a connection between breast arterial calcifications detected on mammography, cholesterol levels, and cardiovascular risk. However, further research is required to gain a comprehensive understanding of the intricate relationship between these factors.

This experimental research aims to investigate the potential of mammography as a screening tool for cardiovascular disease, with a specific focus on postmenopausal women.

MATERIALS AND METHODS

Study Design

This retrospective study involved a total of 1102 women, aged 32-85, who underwent mammography at "Sf. Spiridon" County Clinical Emergency Hospital Iasi from January 2018 to December 2020. The patient's clinical history and laboratory

data were retrieved from the hospital's internal database. The study recorded information on various cardiovascular risk factors, such as hypertension, diabetes, smoking status, total cholesterol levels, diabetes mellitus, and personal history of cardiovascular diseases.

The study group consisted of 95 women who were found to have arterial macro and microcalcification through mammography out of the 1,102 cases analyzed.

The control group consisted of 115 women without arterial calcification, who were age-matched with the patients.

The weight of each patient was divided by their height squared to calculate their body mass index (kg/m^2).

Mammography

All women underwent standard bilateral four-view mammography, with mediolateral oblique (MLO) and cranio-caudal (CC) views, using between 2018 - 2019 a screen-film mammography system Senographe DMR+ and in 2020 a digital unit Senographe Pristina (General Electric Healthcare, Milwaukee, Wisconsin, USA). Mammographies were reviewed on dedicated screens, with a magnifying glass, looking for linear, parallel high intensity opacities (calcifications) within the arterial walls, on either of the two views. Mammography evaluated the presence of calcifications, type (macrocalcifications > 1 mm or microcalcifications < 1 mm), the number of involved arteries, and the distribution. Arterial calcifications can be easily identified due to their distinct pattern on mammography. They appear as linear, parallel high-intensity opacities within the arterial walls (fig. 1).

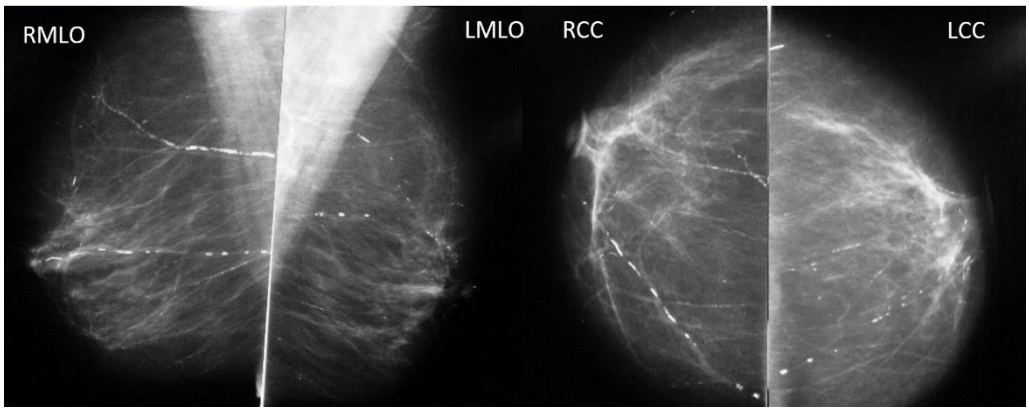

Fig. 1. Screen-film bilateral mammography, MLO and CC views - bilateral arterial calcifications (linear, parallel, high intensity opacities within the arterial walls)

Ethical Considerations

The study was approved by the local Institutional Ethics Committee in keeping with the principles of the Declaration of Helsinki. Data were collected anonymously from the electronic medical records without active patient participation.

Statistical Analysis

The continuous variables were reported as the mean and standard deviation (SD) and the categorical variables were expressed as percentages. Correlations were assessed using Spearman and Pearson coefficients of correlation. Variables between

study groups were compared using a one-way ANOVA test. P-values < 0.05 have been accepted as statistically significant.

The statistical analyses were performed using *Statistical Package for Social Sciences for Mac version 29* (SPSS Inc., Chicago, IL, USA).

RESULTS

Out of the 1,102 cases that were examined, a small percentage of 95 patients (8.6%) displayed the presence of arterial macro and microcalcification on mammography, specifically BAC (+) cases. The average ages of the BAC (+) and BAC (-) groups were 65.7±5.2 years and 59.4±6.3 years, respectively (p < 0.001). In the 60-69 age group, the highest percentage of BAC (+) was observed, reaching 64.21%. The postmenopausal periods for the two groups were 9.3±2.6 years and 6.4±1.9, respectively (p=0.04). Most of the BAC (+) cases were observed in menopausal women (90 cases, 94.73%, p < 0.05).

In the group with breast arterial calcifications, the mean body mass index (BMI) was higher (28.79 kg/m2) compared to the group without arterial calcifications (26.86 kg/m2, p<0.05).

The study revealed a clear link between age and the presence of breast arterial calcifications, with older patients being more likely to have calcifications. Additionally, a slight association was observed between BMI and calcifications, suggesting that higher BMI may be related to calcifications, although it is not a significant predictor (fig. 2).

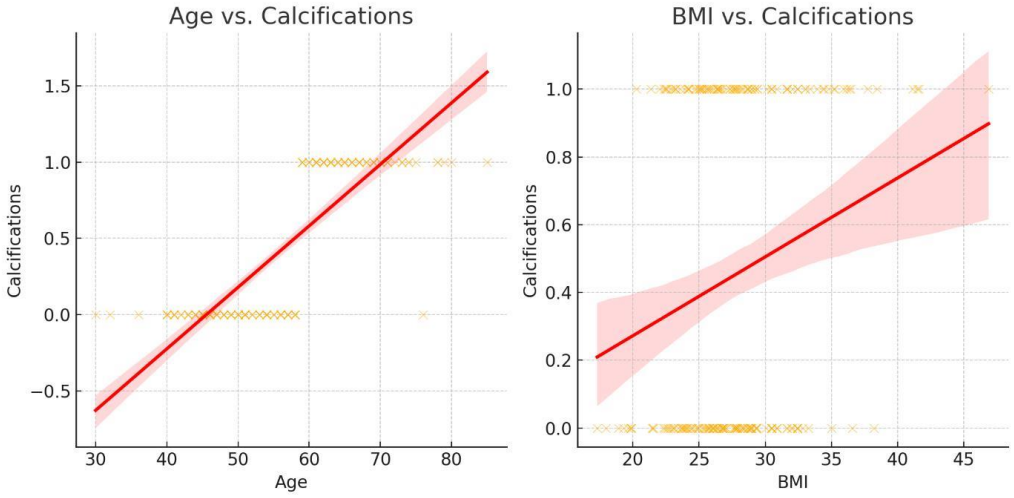

Fig. 2. Scatter plots and regression lines correlating, age, BMI and the presence of breast arterial calcifications.

Further research was conducted on the correlation between breast calcifications and obesity. Out of the individuals with arterial calcifications, only 22 cases (23.15%) had a BMI below 25 kg/m2, indicating a normal weight.

The first table provides a summary of the relationship between the presence of arterial calcifications on mammography and BMI in both, the BAC (+) and BAC (-) groups.

TABLE I.
Relationship between the presence of arterial calcifications and the BMI in BAC+ and BAC- groups

BMI (kg/m2)	< 25 (normal)	25.1-30 (overweight)	> 30.1 (obese)	> 25 (overweight + obese)
Patients, BAC +	22 (23.15%)	41 (43.16%)	32 (33.69%)	73 (76.84%)
Patients, BAC -	35 (30.43%)	55 (47.83%)	25 (21.74%)	80 (69.57%)

The presence of arterial calcifications on mammography was associated with higher mean total cholesterol (256 mg/dL) and LDL cholesterol levels (162 mg/dL) in women, compared to those without breast arterial calcifications (182 mg/dL and 125 mg/dL respectively). Additionally, BAC (+) cases with breast arterial calcifications had a mean HDL cholesterol value of 40 ± 8 mg/dL, while BAC (-) had a mean HDL cholesterol value of 52 ± 10 mg/dL.

The study found a significant difference regarding age, BMI, cholesterol levels (total cholesterol, LDL, HDL), in the study compared with the control. This information is presented in table II.

TABLE II.
Relationship between age, BMI, cholesterol levels and breast arterial calcifications

Characteristics	BAC + (n = 95)	BAC - (n = 115)	p-value
Mean age (years)	65.73 ±5.21	49.38±6.31	< 0.0001
Mean BMI	28.79±5.06	26.86± 3.83	< 0.002
Total Cholesterol (mg/dL)	256± 42	182± 32	< 0.001
LDL Cholesterol (mg/dL)	162 ± 32	125 ± 26	< 0.001
HDL Cholesterol (mg/dL)	40 ± 8	52 ± 10	< 0.05

Our study revealed a notable disparity in the occurrence of calcifications in the breast arteries between women who smoke (27.36%) and non-smoking women (14.78%) with similar calcium deposits ($p < 0.05$).

There was a higher prevalence of cardiovascular diseases (22.10%, $p < 0.05$) and diabetes mellitus (15.78%, $p < 0.05$) among women with breast arterial calcifications compared to those without calcifications on mammography. In contrast, the group without calcifications had a lower incidence of cardiovascular conditions (6.95%) and diabetes mellitus (4.34%). There appears to be a strong correlation between these abnormalities.

The study also included 27 patients diagnosed with cirrhosis. Among them, 10 (10.52%) showed arterial calcifications on mammography, while 17 (14.78%) did not have these lesions. The statistical analysis showed that there was no significant difference between the two groups ($p= 0.343$, NS). There is a negative weak correlation between cirrhosis and breast arterial calcifications, as indicated by the data. It is worth mentioning that the weak correlation is affected by the age of the patients, particularly due to the fact that only 11 of them were over the age of 55.

Associated lesions worth mentioning were fibroadenomas (4 - 4.21% cases in the study group and 6 - 5.21% in the control

group and malignant tumors (23 cases - 24.21% and 17 - 14.78% respectively).

DISCUSSION

The findings of this study reveal a noteworthy connection between BAC and an increased likelihood of an elevated cardiovascular risk. This information derived from mammography suggests that arterial calcifications can indicate a higher risk of cardiovascular problems compared to the general female population, as it suggests that other arteries could also be affected. Although breast arterial calcifications are situated in the media of the arteries rather than the intimal atherosclerotic calcifications found in other arteries, they still pose a considerable risk (23). In addition, BAC on mammography is strongly linked to older age, elevated cholesterol levels, a history of smoking, and diabetes mellitus. This information highlights the dual benefits of detecting arterial calcifications on mammography. It not only serves as a screening tool for breast cancer but also helps identify women at a higher risk for cardiovascular events.

There is a notable correlation between the occurrence of BAC and age. The age group between 60 and 69 years had the highest frequency of observed calcifications among all the patients included. The findings align with the current body of research, indicating that mammography is more likely to detect arterial calcifications in older women (18).

There is a random association between BAC and fibroadenomas and malignant tumors, which are commonly found in the general population. It is quite common for individuals aged 15 to 35 to be diagnosed with fibroadenomas, which are non-cancerous growths. On the other hand, woman over the age of 40 are more prone to being diagnosed with malignant tumors.

This study highlights the coincidental correlation between the presence of BAC and fibroadenomas, which can be attributed to their high prevalence in the general population.

CONCLUSIONS

The underreporting of arterial breast calcification is a common occurrence, as it is generally considered to be a benign condition. However, its association with cardiovascular conditions emphasizes the need for a comprehensive evaluation of patients. Additional research is needed to confirm whether mammography can effectively serve as a screening tool for cardiovascular disease, especially in postmenopausal women.

CONFLICT OF INTEREST AND FUNDING

The authors declare no conflict of interest. This research received no external funding.

THE ESSENTIAL ROLE OF COMPUTED TOMOGRAPHY IN NEURO-ENDOCRINE TUMOR S MANAGEMENT (Abstract): Neuroendocrine tumors (NETs) are a diverse group of neoplasms that arise from neuroendocrine cells throughout the body. Their diagnosis and characterization can be challenging due to their variability in pattern and location. This study **aims** to provide an analysis of NETs demographics, computed tomography (CT) pattern, and correlations among certain characteristics determined after CT examination. **Materials and methods**: Data were collected retrospectively from a cohort of 74 patients with abdominal neuroendocrine tumors and their metastases, diagnosed and followed up using abdominal and pelvic CT from January 1, 2015, to December 31, 2023. We studied variables like age, gender, tumor location, margins, enhancement pattern (appearance on noncontract enhanced, arterial, and portal venous phases), homogeneity, presence of calcifications, lymphadenopathy, and liver metastasis. **Results**: The patient cohort with mean age 65.78 years, contains predominantly females (n=42, 56.8%). The majority of primary tumors were located in the pancreas (n=38, 63,63%) (more specifically in the pancreatic head n=19, 34.54%), and small bowel (n = 10, 18.18%). Most tumors exhibited hypervascularization in the arterial phase (n=68, 91.89%) and only few lesions (7-9.45%) contained calcifications. Liver secondary lesions (31.08%, n=23), and lymphadenopathies (36.5%, n=27 cases) were frequent in the selected cases. **Conclusions**: The demographic data suggest a higher prevalence of NETs in older adults, with a slight female predominance. Males were more likely to have tumors located in the head of the pancreas, while females had a higher incidence of hepatic metastasis. Patients with NET have a high incidence of liver metastases, which requires careful abdominal CT follow-up to evaluate both local and distant extension. CT provides an accurate localization and characterization of NETs but also vital information for staging, prognosis, and correct treatment planning. **Keywords:** COMPUTED TOMOGRAPHY, NEUROENDOCRINE, MANAGEMENT, TUMOR.

INTRODUCTION

Neuroendocrine tumor s (NETs) represent a wide and heterogeneous spectrum of diseases that vary in their primary tumor sites, functional status, and aggressive behavior (1).

They are derived from embryonic neural crest tissue (enterochromaffin cells) and

found in various locations: endocrine glands such as the pituitary, adrenal medulla, and parathyroid glands, as well as endocrine tissue nestled within glandular structures like the thyroid or pancreas, and cells within the exocrine structures like the endocrine cells lining the digestive and tract (2). The gastrointestinal tract (55-67%), the respiratory system (25%) (3), and the pancreas (1-2%) (1, 4) are the primary sites of neuroendocrine tumor development.

NETs are mainly sporadic but may occur in a familial context of autosomal dominant inherited syndromes such as MEN1, MEN2, Von Hippel-Lindau disease, neurofibromatosis type 1 and multiple tuberous sclerosis (4, 5, 6, 7, 8).

Computed tomography (CT) is the most frequently used technique for primary tumor localization, staging, therapeutic monitoring, and follow-up of patients with NETs. Triple-phase intravenous contrast-enhanced CT (early arterial, portal-venous, and equilibrium phases) is usually performed. In primary NETs, the average sensitivity of CT is 73%, a better sensitivity (75%) is attained in detecting extrahepatic metastases, and 80% is reached for liver metastases (9, 10, 11).

MATERIALS AND METHODS

This is a single-center, observational, retrospective study. The patients were selected by searching internal databases of "Sf. Spiridon" County Clinical Emergency Hospital from Iasi, to identify patients who underwent abdominal and pelvic contrast enhanced CT (CECT) from January 1, 2015 to December 31st 2023, for suspicion of NET or for evaluation treated NETs and we depicted 74 patients.

Abdominal and pelvic CT was performed with a 64-detector Incisive Philips CT scan; All patients ingested 1,500 ml water in one hour to distend the stomach and small bowel, and underwent colonic cleansing preparation followed by a 1500-2000 ml water enema before the procedure.

An abdominal and pelvic noncontrast enhanced scan was performed, then we injected intravenously up to 120 mL of 370 I/mL Iomeprol (Iopamiro 370 mg/mL), with an automatic injector, with the speed of 3 - 4 ml/second, followed by 50 ml of saline chaser; we measured with bolus tracking technique the densities during contrast injection in the descending aorta above the diaphragm; when the density was over 120 HU, the scanning started with a delay of 7 seconds for the arterial phase, 60–70 s for the portal venous phase, and 3-4 minutes for the equilibrium phase (11,12,13).

We studied variables like age, gender, tumor location, margins, enhancement pattern (appearance on non-contrast enhanced, arterial, and portal venous phases), homogeneity, presence of calcifications, lymphadenopathy, and liver metastasis.

Descriptive statistics were calculated for all variables. Frequency distributions were analyzed for categorical variables. Pearson and Spearman correlations were performed to identify relationships between continuous and categorical variables, respectively. Statistical significance was set at $p<0.05$. Our institutional review board approved the study.

RESULTS

The cohort comprised 74 patients diagnosed with NETs, who had a mean age of 65.78 years (SD 12.49), an age range of 32–88years, and a slight female predominance (56.8% female, 43.2% male). The median age for both male and female patients is relatively similar. The majority of

patients fall within the 58–74 years age range, reflecting that in our study most of the patients were middle aged and elderly. This demographic profile aligns with existing literature, suggesting that NETs predominantly affect older adults, with a slight predominance in females.

The majority of newly diagnosed primary tumor s (n=55) were located in the pancreas (n=35, 63.63%). The most common locations for primary tumor s were found in the pancreatic head (n=19, 34.54%), and small bowel (n = 10, 18.18%). Other notable locations include the pancreatic body and tail (n=9, 16.36% each), mesentery and stomach (n=4, 7.27%). Rare locations include appendix, cecum and adrenal gland (n=1, 1.81% each). This distribution highlights the pancreas and small bowel as primary sites for NETs in our study, emphasising the importance of searching for these organs when a neuroendocrine tumor is suspected.

The median age for NETs localized in the pancreatic head was around 70 years, while patients with tumor s localized in the pancreatic body (median age 55), small bowel, or stomach tend to be younger (both with a median age of 60).

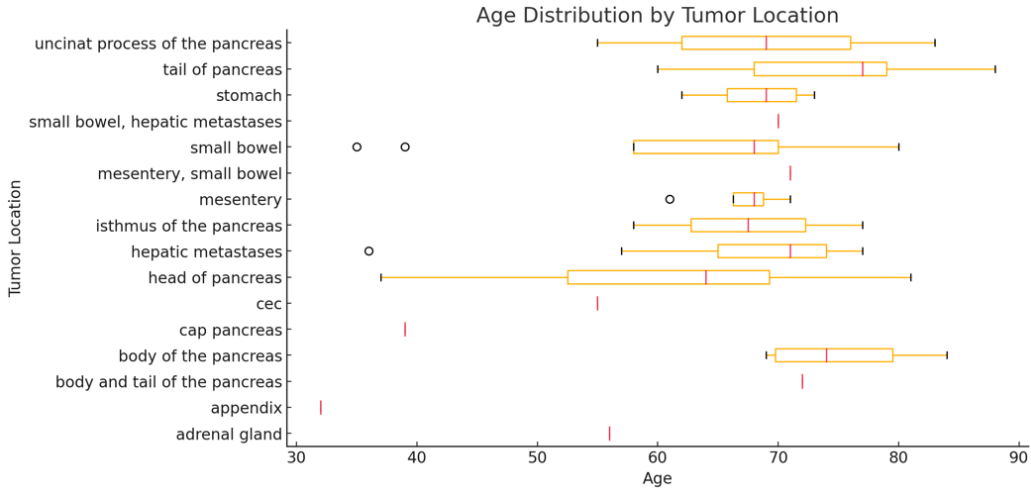

Fig. 1. Age distribution of patients across different tumor locations

Adenopathy, which is a critical factor in staging and prognosis, was observed in 36.48% of patients (n=27), while local invasion was detected in 21.6% (n=16), reflecting the aggressive nature of some tumor s and necessitating a treatment approach.

The most frequent primary tumor s associated with adenopathy's had the following locations in descending order: pancreatic head (n=9, 12.16%), mesentery (n=4, 5.4%), small bowel (n=3, 4.05%), stomach (n=2, 2.7%).

Liver secondary lesions were found in case of surgically treated followed-up patients in 19 (25.67%), but also in newly diagnosed primary tumor s. These data are similar with ones in the literature, highlighting that the liver is a common site for metastatic spread in NETs. All the tumor s located in the mesentery have hepatic secondary lesions, emphasizing the need for

carefully monitoring these patients for potential liver metastasis. Also, 11 patients out of 19 with secondary liver lesions had adenopathies present. Patients with hepatic metastasis have a slightly higher median age (70 years) compared to those without hepatic metastasis (68 years). Elderly were significantly associated with the presence of hepatic metastasis ($p<0.05$).

Various density patterns were observed in noncontrast enhanced, arterial, and venous, phases (fig. 2). On the non-contrast enhanced phase, the majority of tumor s are izodense (n=51, 68.92%), with only 20 (27.03%) hypodense tumor s, and 3 (4.05%) hyperdense tumor s. Most tumor s exhibited hypervascularization in arterial phase (hyperdense, n=68, 91.89%; izodense, n=2, 2.70%; hypodense, n=4, 5.41%). The majority of tumor s (87.8%) showed important, homogeneous enhancement in the arterial phase, while other patterns like discrete enhancement (4.1%), peripheral enhancement (2.7%), and progressive enhancement (2.7%) were rare. A high amount of tumor s remains hyperdense (n=54, 72.97%) in the portal venous phase; 9.47% were hypodense (n=7) and 17.57% izodense (n=13). 62 tumors (83.78%) had well-defined margins while 16.22% (n=12) have ill-defined margins, these last ones having also important enhancement; therefore, the hyper vascular lesions were more likely to show local invasion ($p<0.01$).

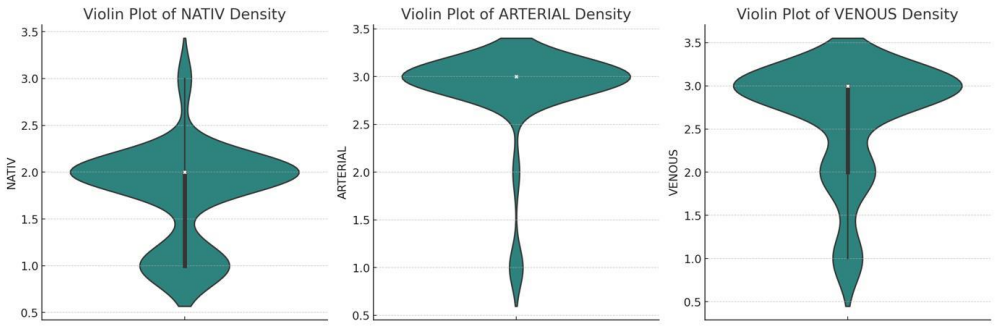

Fig. 2. Violin plot showing the correlation between NETs densities in noncontrast enhanced, arterial and portal venous phase

Less lesions were homogenous 28 (37.84%), and most of them were heterogeneous (n=46, 62.86%), with a strong positive correlation between heterogeneous tumor s and poorly defined tumoral margins ($p<0.001$). There is a borderline significant difference ($p= 0.051$), which potentially suggests that age might be linked to homogeneity, this potential trend can be explored further with a larger sample size. The elder age might be linked to tumor heterogeneity. Inhomogeneous tumors are more likely to be associated with hepatic metastasis compared to homogeneous tumors ($p< 0.05$).

Calcifications were present only in 7 cases (9.45%), with a majority of 67 patients (90.55%) showing no calcifications. Calcifications are present in 11.76% of tumor s located in the pancreatic head and in 11.11% of tumor s located pancreatic tail or small bowel. A higher percentage (50%, 2 of 4 cases) of tumor s located in the mesentery had calcifications. The presence of

calcifications can be associated with certain NETs locations (pancreatic, small bowel, mesentery) and might influence the choice of imaging modality and interpretation of results.

DISCUSSION

The characterization of this cohort highlights several critical aspects of NETs. The demographic data suggest a higher prevalence in older adults, with a slight female predominance. Males were more likely to have tumor s in the head of the pancreas, while females had a higher incidence of hepatic metastasis. The majority of patients are aged between 55 and 75.

Imaging features on CT scans revealed distinct patterns among the tumor s. Enhancement patterns were particularly notable, with 91.89% of tumor s showing significant enhancement in the arterial phase, which is indicative of the vascular nature of NETs.

The majority of tumor s were located in the pancreas (63.63%), specifically the head (19%). Other common sites included pancreatic tail and the small bowel. This distribution highlights the pancreas as the primary site of interest for NETs, emphasizing the importance of these locations in diagnostic and therapeutic strategies.

Adenopathy (a critical factor in staging and prognosis) was observed in 36.5% of patients, while local invasion was detected in 21.6%, reflecting the aggressive nature of some NETs, necessitating a differentiated treatment approach.

The high incidence of hepatic metastasis (25.67%) aligns with the known behaviour of NETs to metastasize to the liver, impacting patient management significantly and suggesting a need for regular liver monitoring. Older age is associated with the presence of hepatic metastasis in patients with neuroendocrine tumor s, which might suggest that metastatic disease is more common as patients' age increases. In the noncontrast enhanced phase, most tumors were izodense (68.9%), while in the arterial phase, a majority were hyperdense (91.9%). The venous phase also showed a high percentage of hyperdense tumor s (73.0%). These enhancement patterns reflect the dynamic vascular nature of NETs, which can be leveraged in both diagnostic imaging and interventional procedures.

Homogeneity and limits of the tumor s were also assessed, with 62.86% being heterogeneous and 83.78% well defined. Calcifications were observed in 9.45% of patients.

These imaging characteristics are crucial for an accurate diagnosis and can influence treatment. Neuroendocrine tumors are sometimes correlated with diabetes and various infections (13, 14). We are looking forward to apply artificial intelligence and machine learning in the diagnosis and management of gastroenteropancreatic neuroendocrine tumors (15).

CONCLUSIONS

The gender-based differences in tumor location highlight potential underlying biological mechanisms warranting further investigation.

The detailed analysis of enhancement patterns across different CT phases provides valuable insights into the vascular properties of these tumor s. These imaging features not only aid in diagnosis but also have potential implications for treatment, particularly in planning surgical or interventional procedures.

High incidence of liver metastatic involvement necessitates frequent liver monitoring in case of patients diagnosed with

NETs, since early detection of metastasis can significantly impact management and outcomes.

CT imaging not only aids in the accurate localization and characterization of NETs but also provides essential information on metastatic spread and associated adenopathy. and provide vital information for an accurate staging, prognosis, and treatment planning.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no funding.

WIDE AWAKE LOCAL ANESTHESIA NO TOURNIQUET (WALANT) IN HAND SURGERY - A RETROSPECTIVE STUDY ON 400 CASES. (Abstract): The study **aimed** to evaluate and confirm the efficacy and safety of WALANT anesthesia in hand surgery. **Materials and methods**: A retrospective analysis was conducted on 400 hand surgeries performed under WALANT between January 2020 and December 2023. Diseases included carpal tunnel syndrome (CTS), Dupuytren disease (DD), trigger finger (TF), also tendon injuries, phalangeal and metacarpal fractures, and tumor excisions. Data collected included patient demographics, anesthetic dosage, onset time, dilutions, intraoperative incidents (pain, bleeding, discomfort), complications, surgical duration, hospitalization, patient satisfaction (VAS), and functional outcomes (DASH and MHQ scores). Statistical analysis was performed using *SPSS version 29.0*, with regressions (ANOVA) and Pearson correlation coefficients. **Results:** The mean hospitalization time was 3.5 hours, with 95% of patients discharged the same day. Complications were low (5%), and functional outcomes improved significantly, with DASH scores improving by 66.7% on average. No cases of digital necrosis or other vascular complications occurred. **Conclusions**: WALANT is a safe, effective, and resource-efficient technique for hand surgery. It optimizes hospital resources, enhances patient outcomes, minimizes costs, and supports sustainable healthcare. **Keywords:** LOCAL ANESTHESIA, WALANT, HAND SURGERY, LIDOCAINE, EPINEPHRINE.

INTRODUCTION

The advancement of hand surgery, orthopedic surgery, and various other surgical disciplines has been markedly enhanced by the integration of minimally invasive anesthetic techniques, such as WALANT (Wide Awake Local Anesthesia No Tourniquet) (1). In the early 2000s, Donald Lalonde pioneered the use of a combination of local anesthesia (1% lidocaine) and epinephrine (1: 100,000) to develop WALANT for vasoconstriction, creating a bloodless surgical field without the need for general anesthesia or tourniquets (2). This technique allows

real-time functional testing while keeping patients awake, improving precision, safety, and recovery times (3). While initially popularized in hand surgery for pathologies like tendon injuries, carpal tunnel syndrome and fractures, it has proven effective in a variety of other surgical domains (4). Hand surgeries relied on general or loco-regional anesthesia in combination with a tourniquet, a practice associated with risks such as pain, nerve damage, and prolonged recovery. The WALANT technique, utilizing a solution of 1% lidocaine with epinephrine (1: 100,000), provides local anesthesia and a bloodless surgical field, while eliminating the complications and risks associated with tourniquet use and the need for additional sedation required with other anesthetic methods (2-5).

Early concerns about the safety of epinephrine in hand surgeries were alleviated through studies demonstrating its safety at low concentrations, leading to WALANT's global acceptance (5, 6). Lalonde *et al*. was initially cautious about using epinephrine in hand surgeries due to concerns over necrosis from intense vasoconstriction. He indicated the use of phentolamine as an antidote (7, 8). This type of local anesthesia is indicated and effective in hand surgeries, including both acute trauma cases and chronic pathologies, as well as in palliative hand surgery (9, 10). It has also shown significant advantages in orthopedic surgery, including clavicle fractures, distal radius fractures, ankle fractures, metatarsal fractures, and certain types of joint procedures (11). WALANT's localized approach also reduces risks associated with systemic anesthesia, making it a safer option for patients with comorbidities. Most patients can be safely discharged within a few hours of the procedure, with minimal postoperative care required due to the rapid recovery associated with WALANT, improving hospital efficiency and patient satisfaction (11-13).

By eliminating the need for anesthesia personnel, extensive monitoring, and recovery units, it has significantly lowered the cost of surgeries (14). As a green surgical technique, WALANT contributes to sustainable practices by reducing medical waste and resource utilization. Its impact on modern surgical practices across hand surgery, orthopedics, reconstructive surgery, and palliative care highlights its versatility and transformative potential (15). Due to the fact that this study was conducted during the COVID-19 pandemic, specific challenges emerged regarding patient care and safety (16). In this context, the adoption of WALANT has emerged as the preferred, and often the sole feasible approach for patient management, establishing it as a gold standard in hand surgery anesthesia (17-19). A retrospective study was conducted on 400 hand surgeries performed under WALANT between January 2020 and December 2023. All surgeries performed under WALANT anesthesia.

MATERIALS AND METHODS

A retrospective study was conducted on 400 hand surgeries performed under WALANT between January 2020 and December 2023. All surgeries were done at Plastic and Reconstructive Surgery Clinic from the Emergency County Hospital "Sf. Spiridon" of Iasi. On admission, the informed consent was obtained from all patients in the study group. The ethics committee of the hospital has granted approval for the reporting of the present study. The inclusion criteria for the study group were as follows: patients over 18 years of age undergoing hand surgery with indication of local anesthesia - carpal tunnel syndrome,

trigger finger, Dupuytren disease, tendon injuries or tenolysis, metacarpal and phalangeal fractures, patients who consented to this type of anesthesia, patients with no known allergies to lidocaine or epinephrine, ability to remain awake and tolerate the procedure. Exclusion criteria were: patients under 18 years old, patients who did not consent for this type of anesthesia, pathologies including vascular damage involving microsurgery or intricate vascular techniques, patients with psychiatric or neurological conditions impairing their ability to remain calm during surgery, patients with significant cardiac conditions contraindicating the use of epinephrine. The recorded data were collected from the medical records (observation sheet and the hospital's electronic information system) of hospitalized and treated patients. In the studied group, were registered: epidemiological data (age, gender, urban or rural residence) comorbidities, diagnosis, the amount of anesthetic used, the dilutions used, waiting time until its onset, intraoperative incidents/accidents (pain, bleeding, doctor/patient discomfort), duration of the surgery, functional outcomes (with DASH scale) measured at 6 weeks and 3 months, complications, hospitalization time and patient satisfaction level using VAS scale. In all instances, surgical procedures were conducted under local anesthesia using a solution of 1% lidocaine with epinephrine in a concentration of 1: 100,000 or 1: 200,000. Sodium bicarbonate (8.4%) was not used for buffering in any case. Pain during the procedure was objectively monitored through vital signs (blood pressure, heart rate) and subjectively through patient feedback, describing pain as non-existent, minimal, tolerable, or intolerable. Patient comfort was assessed both by tracking vital signs and through their subjective response.

Statistical analysis. The data were analyzed using *SPSS Version 29*, with the following statistical techniques: descriptive statistics for demographic data, anesthetic use, and hospitalization time, chi-Square Tests to analyze differences in complication rates between different types of surgeries, paired T-Test for comparing preoperative and postoperative DASH scores, ANOVA for comparing costs and outcomes across different surgical procedures, regression Analysis to identify predictors of postoperative functional outcomes, including age, comorbidities, and anesthetic volume

RESULTS

The gender distribution in the research cohort is represented by 55% male patients with a male/female = 1/1.22 The age of the patients ranged from 18 to 85 years, with a mean age of 50.6 years. The analysis showed that 70% of patients came from urban areas, consistent with findings in WALANT literature, where urban settings dominate due to the technique's accessibility in outpatient centers. However, the remaining 30% rural representation in the data reflects a notable proportion of trauma cases, which may be associated with labor-intensive occupations common in rural regions. The largest proportion of patients was aged 31-50 years (40%), followed by 51-70 years (32.5%), reflecting the prevalence of working-age adults in the study cohort. Carpal tunnel syndrome (CTS) was the most frequently treated condition (29%), followed by flexor and extensor tendon injuries 26,75%), metacarpal and phalangeal fractures (18.5%), trigger finger (TF) (12%), Dupuytren's disease (DD) (7%), and other surgeries (6.75%) (tab. I).

TABLE I.
Demographic data of the studied group

CTS= carpal tunnel syndrome, TF= trigger finger, DD= Dupuytren disease, y=year

Patients were instructed to inform the surgeon if they experienced any pain or discomfort, even if minor. Initially, 0.3 to 0.5 mL of anesthetic was injected just beneath the dermis. Once the patient no longer reported pain, the remainder of the anesthetic was administered by advancing the needle to a depth of approximately one cm. The total anesthetic volume did not exceed 20 mL for CTS and 15 mL for each affected digital ray in cases of DD. The volume of anesthesia used and its dilution were key factors influencing both the quality of the surgical field and patient satisfaction (fig.1). Procedures that required higher volumes of anesthesia (e.g., DD) often used higher dilutions, which led to a lower incidence of complications such as intraoperative bleeding. For instance, the 1: 200,000 dilution of epinephrine provided an optimal balance between pain control and vasoconstriction, ensuring effective hemostasis during the surgery while maintaining patient comfort, confirming that the 1: 200,000 dilution allowed for rapid onset and reduced intraoperative bleeding. The reduced anesthesia volume (10-14 mL) used in the cohort group aligns with the WALANT principle of minimizing invasiveness without sacrificing efficacy (fig. 1).

For CTS cases, 10 mL the anesthetic solution was injected on each side near the incision site, and the remaining 10 mL was administered into the surrounding skin area where hypoesthesia was already present. This method was similarly employed in DD cases, with the anesthetic being injected around the planned incision sites. In TF cases, no more than 1 mL of anesthetic solution was injected into each affected phalanx. Throughout the anesthetic administration, patients were conscious, cooperative, and did not receive any sedatives. The onset of anesthesia occurred within 6 to 15 minutes (tab. II).

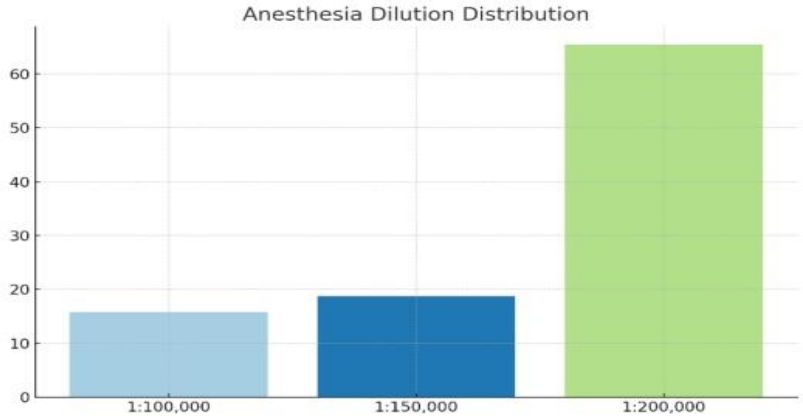

Fig. 1. Anesthesia dilution distribution

TABLE II.

Anesthesia installing time (minutes)

Range	Number	Percentage	Mean Total Group (Max / Min)	Other Metrics
< 10 min	34	8.5%		TF: 7.84 (10/5)
10-14 min	207	51.67%	13.93 (20/8)	Tendon injuries: 11.2 (14/7) CTS: 11.41 (15/8), Other: 12.31 (20/5)
15-20 min	159	38.75%		DD: 16.41 (20/8), Fractures: 14.82 (20/8)

TF-trigger finger; DD- Dupuytren's disease

Key finding from the study is the reduced hospitalization time. Percentage of patients were discharged within 3-4 hours post-surgery (fig. 2).

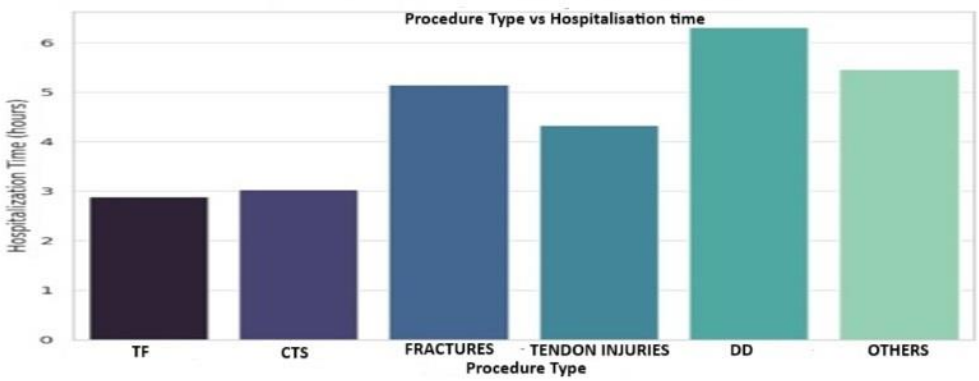

Fig. 2. Procedure type *vs.* hospitalization time

The amount of anesthetic solution used was 10-14 mL in almost half of the cases (49%), with a mean volume of 14.61 mL across the entire group. Subgroup analysis revealed that Dupuytren disease required the highest mean anesthetic volume (18.92 mL) but still under 20-25 mL how literature recommend, while trigger finger required the lowest (4.13 mL) (tab. III). These findings indicate that even if there are more complex procedures, such as those for Dupuytren's disease, which typically necessitate higher volumes of anesthetic to ensure adequate analgesia and hemostasis, lower volume with higher dilution can have good results (tab. IV).

TABLE III.

Anesthetic solution (mL)

Range	Number	Percentage
< 10 mL	37	9.25%
10-14 mL	196	49%
15-19 mL	134	33.5%
>= 20 mL	31	7.75%

TABLE IV.

Mean values by group (anesthetic solution)

Group	Mean (Max/Min)
Total Group	14.61 (20/2)
TF	4.13 (5/2)
CTS	15.43 (20/14)
Fractures	17.33 (20/15)
Tendon Injuries	8.53 (10/6)
Dupuytren's Disease	18.92 (20/10)
Other	11.37 (12/10)

Calculating the Pearson correlation coefficients and their p-values based on the cohort patients collected data the study revealed: Anesthesia Volume *vs.* Onset Time - Correlation coefficient (r): 0.99, p-value: 0.011. There is a strong positive correlation between anesthesia volume and onset time, meaning higher anesthesia volumes are associated with longer onset times. Anesthesia volume vs. satisfaction - correlation coefficient (r): -0.998, p-value: 0.002. There is a very strong negative correlation, indicating that higher anesthesia volumes are associated with lower patient satisfaction (fig.3). Dilution Level vs. Satisfaction. Correlation coefficient (r): -0.994, p-value: 0.006. There is a strong negative correlation, suggesting that higher dilution levels are associated with higher patient satisfaction. These results are statistically significant (p-value < 0.05), supporting the hypothesis that lower anesthetic volumes and more diluted solutions can lead to shorter onset times and higher patient satisfaction (fig. 3).

Hospitalization time differed significantly by procedure type, with shorter stays noted for simpler procedures like carpal

tunnel syndrome ($p < 0.001$). The absence of a tourniquet and the localized anesthesia significantly reduced the discomfort commonly associated with traditional methods. In terms of complications, the study recorded a no accidents or incidents during surgery. There were no instances of digital necrosis or vascular complications, demonstrating the safety of WALANT in this cohort. The absence of significant intraoperative bleeding or the need for epinephrine reversal agents, such as phentolamine, further supports the effectiveness of WALANT as a reliable and safe anesthetic technique.

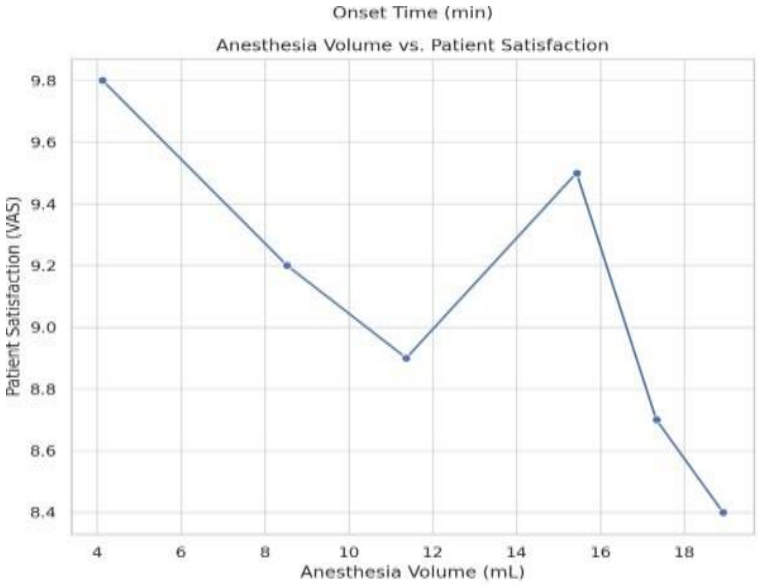

Fig. 3. Anesthesia volume *vs.* patient satisfaction

Patients in the older age groups, particularly those aged 51-70 and 71-85 years, experience longer hospital stays. This increase in hospitalization time can be attributed to several factors. Older patients are more likely to have multiple comorbidities, such as diabetes or cardiovascular diseases, which can complicate both surgery and recovery. Additionally, age-related physiological changes, such as reduced tissue healing capacity and a higher likelihood of postoperative complications, may necessitate prolonged monitoring and care (fig. 4).

Patient satisfaction was assessed using a Visual Analog Scale (VAS) and DASH scores, at 3 weeks and 6 months with results indicating high satisfaction rates. The average VAS score for pain during the procedure was low, ranging from 0 to 2, demonstrating that the anesthesia provided adequate pain relief. Furthermore, satisfaction was correlated with the volume and dilution of the anesthetic. Higher volumes of anesthesia, especially when diluted appropriately, contributed to better pain control and comfort during the procedure. Notably, patients reported less discomfort and quicker recovery times when larger dilutions (greater than 1: 200,000) of lidocaine with epinephrine were used, resulting in a bloodless surgical field with minimal pain (tab. V).

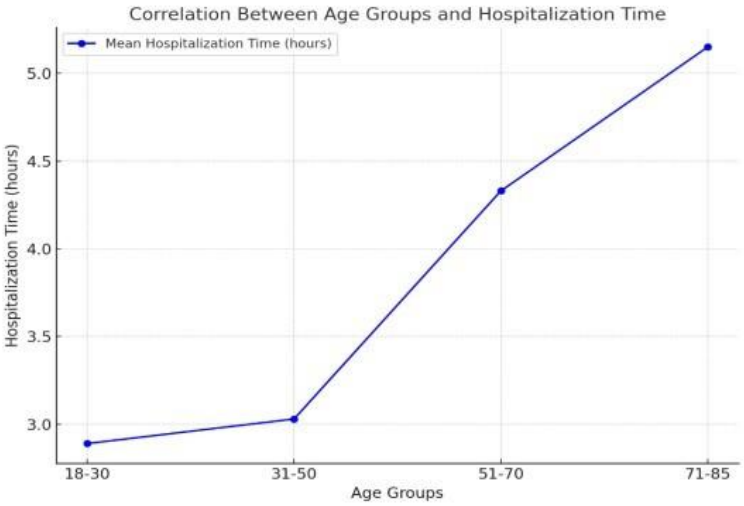

Fig. 4. Correlation between age groups and hospitalization time

DISCUSSION

The application of WALANT, particularly in trauma-related surgeries, compared to its predominant use for elective procedures in the literature. These differences likely reflect the demographic and clinical characteristics of the patient population, demonstrating WALANT's versatility in addressing both degenerative and trauma-related conditions (19, 20).

A significant reduction in hospitalization time, with the majority of patients being discharged within 3-4 hours, compared to the 4-6 hours of hospitalization typically reported in WALANT literature. Studies like Lalonde (2005) and Fitzcharles-Bowe (2007) suggest that WALANT procedures usually require about 4-6 hours of observation (21, 22). This study highlights the potential for even shorter hospital stays, indicating that using lower anesthetic volumes can streamline

recovery and enhance discharge efficiency without compromising patient safety.

As it for demographics, this cohort, with 40% of patients aged 31-50, contrasts with the older demographic typically reported in WALANT studies, where patients are usually aged 50-55 years (Fitzcharles-Bowe, 2007; Casal *et al*., 2011) (23, 24). The younger patient population in this study likely reflects a higher proportion of trauma-related surgeries, such as tendon injuries and fractures, which are less commonly explored in WALANT studies focused on elective procedures. This finding underscores WALANT's versatility in handling both degenerative and trauma-related conditions, extending its application beyond what is usually seen in the literature.

The study used significantly lower anesthetic volumes (10-20 mL), compared to the 20-40 mL often reported in other WALANT studies (e.g., Martin *et al*., 2005) (25). These reduced volumes were sufficient for adequate pain control, aligning with WALANT's principle of minimizing invasiveness. This result contrasts with studies by Lalonde (2005) and Kalle *et al*. (2010), which employed larger volumes of anesthesia and possibly had higher complication risks (26). Moreover, study highlighted that higher dilution of local anesthetic contributed significantly to both the safety and effectiveness of the procedure. The 1: 200,000 dilution of epinephrine used in the study group was more diluted than in many studies, where concentrations typically range from 1: 100,000 to 1: 150,000. This higher dilution allowed for better pain management and reduced the risk of complications such as excessive vasoconstriction and intraoperative bleeding (27). The surgery for carpal tunnel syndrome (CTS) tends to have shorter recovery times (Lalonde, 2005; Foucher *et al*., 2015), this study demonstrated that WALANT is equally effective for more complex procedures, such as metacarpal and phalangeal fractures and Dupuytren's disease (DD), which require higher anesthesia volumes (26). However, even these complex surgeries benefited from higher dilution (1: 200,000), which allowed for minimal complications and quicker recovery (28-30). The study's safety profile, with no accidents or complications, is consistent with the low complication rates reported in the literature, though it exceeds other studies that recorded rare complications (31). The absence of digital necrosis, vascular complications, or the need for reversal agents further supports the effectiveness and safety of WALANT when lower volumes and higher dilutions are used. This emphasizes the safety of WALANT, especially in more complex surgeries, where other studies report a higher likelihood of complications (32).

CONCLUSIONS

Considering the numerous advantages of the WALANT technique, including its rapid onset of anesthesia, efficiency, and safety profile, as well as the wide range of surgical procedures it facilitates, it represents a highly effective alternative to classical anesthesia techniques. WALANT is associated with minimal risks, significantly reduced waiting and hospitalization times, and eliminates the need for preoperative fasting or complex monitoring. Moreover, it contributes to increased patient satisfaction by providing a comfortable and awake surgical experience with

faster recovery. Given these benefits, WALANT could be regarded as a gold standard for elective or emergency hand surgery procedures.

PARTIAL SPLENIC EMBOLIZATION-MINIMALLY INVASIVE ALTERNATIVE TO SURGICAL SPLENECTOMY IN THROMBOCYTOPENIC HYPERSPLENISM. A SINGLE CENTER EXPERIENCE (Abstract): Partial splenic embolization (PSE) is a minimally invasive procedure that replaced radical surgical intervention of splenectomy for the treatment of severe cytopenia, mainly life-threatening thrombocytopenia secondary to hypersplenism in advanced liver disease. **Materials and methods:** This is an observational, retrospective and analytical study of 15 patients undergoing PSE from "St. John" Emergency Hospital Bucharest, admitted to Gastroenterology Clinic for several complications of liver cirrhosis, during May 2013-July 2019, while the patients' survival rate was followed up until November 2024. **Results:** Our results confirm once again that PSE is a reliable nonsurgical technique used to improve the consequences of hypersplenism associated with portal hypertension in chronic liver disease, especially in liver cirrhosis. Generally, the postembolization course was uneventful; non-severe complications developed and were properly managed by conservative treatment. **Conclusions:** A significant improvement of platelet number was obtained in all patients, allowing better outcome for each case, especially if a surgical intervention is scheduled. **Keywords:** PARTIAL SPLENIC EMBOLIZATION, THROMBOCYTOPENIA, LIVER CIRRHOSIS.

INTRODUCTION

Liver cirrhosis is an important public health issue due to its several complications related to portal hypertension that accompanies the advanced stages: variceal bleeding, hepatic encephalopathy, hepatorenal syndrome and sometimes hepatopulmonary syndrome (1, 2). Splenomegaly is a sign of portal hypertension and is responsible for hypersplenism development as an overactive splenic function of destruction the blood cells. Historically, the term "hypersplenism" was first mentioned in a paper of Anatole Chauffard in 1907, and after that in 1955, the German physiologist Morawitz defined hypersplenism related to liver diseases, while the German surgeon Denecke described the triad of hypersplenism: spleno-

megaly, peripheral cytopenia, normal or hyperplastic bone marrow (3,4). Among all consequences of hypersplenism, thrombocytopenia is the most relevant one in chronic liver disease for the biological coagulation status, because it enhances the coagulopathy of cirrhotic patient (5). Hepatic dysfunction together with severe decrease of platelet count are the major factors that potentially make the cirrhotic patients a poor surgical candidate. Thus, any attempt to increase the level of circulating platelets gained a lot of interest. Considering the per operative risks of surgical splenectomy in patients with advanced liver disease, PSE became widely used instead, being safer on one hand, and on the other hand, more efficient due to preservation of immunological role of spleen (6, 7, 8). The increase in platelet ratio is related to the volume of spleen targeted for embolization, which has been demonstrated to correlate also with the severity of post-procedural complications (9, 10). It has been stated that almost 50 % of splenic volume needs to be devitalized in order to obtain an efficient improvement of thrombocytopenia (11, 12). In fact, the goal of procedure is to achieve approximately 50-70% of spleen embolized. Major and minor complications can develop after PSE, but the majority of them are non-severe and controllable through conservative therapy, post-embolization syndrome being the most frequent encountered (13,14).

MATERIALS AND METHODS

This retrospective study involved 15 patients with pancytopenia or only with thrombocytopenia, 14 patients with chronic liver disease and one patient with a hematological condition, who underwent PSE. The goal of the study is to identify certain relationships between biological parameters pattern, especially increase in platelet or leucocyte number, the occurrence of complications and the prognosis of patients. In order to assess if the postprocedural increase in the blood indices was significant, it was crucial to choose the right statistical test.

The procedure was performed using Seldinger technique, that is percutaneous catheterization of a peripheral artery, the common femoral artery in these cases, after local anesthesia. A 5 Fr catheter was inserted into the celiac trunk via femoral artery, and after that selective catheterization of splenic artery was achieved using a 2,8 Fr microcatheter and placing it as distal as possible from the hilum to obtain the embolization of segmental splenic branches (figs. 1, 2). The material used for embolization was a gelatin foam and the procedure required contrast medium injection and fluoroscopic control.

A subgroup of patients was followed up over a period of 11 years, thus enabling the assessment of survival rate for this certain group. The remaining subjects were lost from observation due to lack of presentation at scheduled appointments.

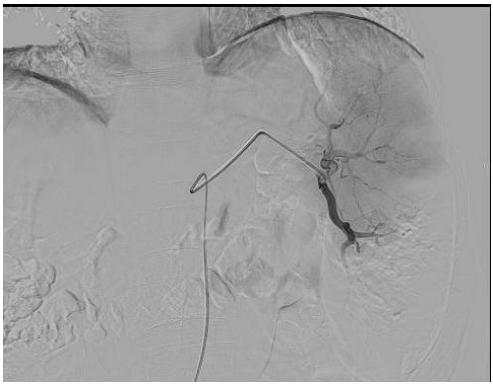

Fig. 1. Supraselective catheterization of the inferior terminal branch of the splenic artery.

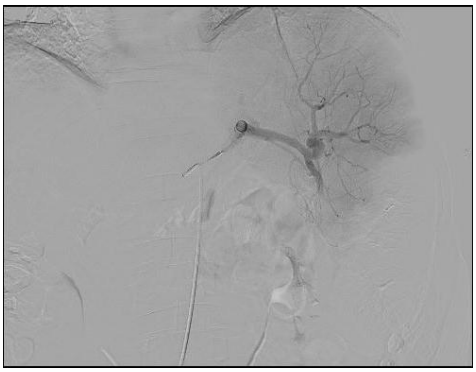

Fig. 2. Injection of embolic material was performed into the inferior branch of splenic artery.

The analysis process included several stages: data collection from patients electronic or paper files; data processing; testing the normal distribution for each continuous variable (Shapiro-Wilk; histograms); using the right statistical test (t-test, Wilcoxon, Mann-Whitney, Pearson/Spearman, Chi-square); graphic representation of biological parameters dynamics through box plot, linear graphs and scatterplots; results interpretation depending on statistical significance ($p< 0.05$) and clinical relevance.

We used different tools: Microsoft Excel for initial data analysis; SPSS / R / Jamovi / Python (pandas, scipy, matplotlib) for advanced statistical analysis; GraphPad Prism / Tableau / ggplot2 for data visualization (optional).

A preliminary step before applying statistical significance tests (parametric and nonparametric) consisted of verifying the normality of data distribution for each analyzed variable. This step is of extremely importance because the parametric test (as t-test for paired samples) involves a normal distribution of differences, while the nonparametric test (as Wilcoxon test) doesn't imply this condition. So, for each of these three variables-thrombocytes, hemoglobin and leukocytes- we applied **Shapiro-Wilk** test, considered adequate for small samples, for assessing whether the differences pre-postprocedural follow a normal distribution.

The results of this test will determine the subsequent choice of statistical comparison method (tab. I).

TABLE I.
Normality Test-Shapiro-Wilk

Variable	Normality (p Shapiro-Wilk)	Conclusion
Thrombocytes	$p < 0.05$	Abnormal distribution
Leukocytes	$p > 0.05$	Normal distribution
Hemoglobin	$p > 0.05$	Normal distribution

Based on Shapiro-Wilk test, we used: for thrombocytes nonparametric *Wilcoxon test* for paired samples, for leukocytes parametric paired *t-test* and for hemoglobin parametric paired *t -test.*

The use of Shapiro-Wilk test ensures accurate selection of the statistical tool, avoiding misinterpreting due to incorrect assumptions of data distribution.

For each variable (thrombocytes, hemoglobin and leukocytes), we stated the following hypothesis:

- **Nule Hypothesis (H0):** there is no significant statistical difference between pre and post-treatment values.
- **Alternative Hypothesis (H1):** there is a significant statistical difference between pre and post-treatment values.

RESULTS

We focused on different characteristics of the patients, including demographic, clinical and biological data.

The age of the patients was between 28 and 78 years, with a median age of 56.8+/- 13.8 years per patient. Males 'age ranged between 38 and 72 years with a median age of 57.7+/- 13.1 year per patient, while females have ages between 28 and 78 years with a median of 56.2+/- 15.1 per patient. According to Shapiro-Wilk test (p= 0.914), the distribution of variable "Age" indicates a normal distribution of subjects.

The majority of study participants, 14 patients suffered from chronic liver disease, with viral (hepatitis virus B, B+D or hepatitis C) or alcoholic etiology, while only one patient exhibited a hematologic disease, which in fact had an "off labeled" indication for PSE and did not respond in a favorable manner after the procedure.

Considering the statistical methodology presented earlier, we obtained the following results:

Thrombocytes:

- Shapiro-Wilk test showed an abnormal distribution (p = 0.004).
- The nonparametric Wilcoxon test was used.
- The result is statistically significant (p = 0.041), indicating a **significant difference** between pre and post intervention values, with a postprocedural increase of platelet level.

Leukocytes:

- The distribution of differences is normal (p = 0.10).
- The parametric paired t-test was used.
- The result is statistically significant (p = 0.002), showing a **significant difference** between pre and post intervention levels, with a postprocedural increase of leukocytes

Hemoglobin:

- The distribution of differences is normal (p = 0.98).
- The paired t-test exhibits a significant difference (p=0,328), suggesting a **slightly increase**, but non-significant, of hemoglobin after PSE.

The fluctuations of hematological parameters pre and post embolization are illustrated in the third figure.

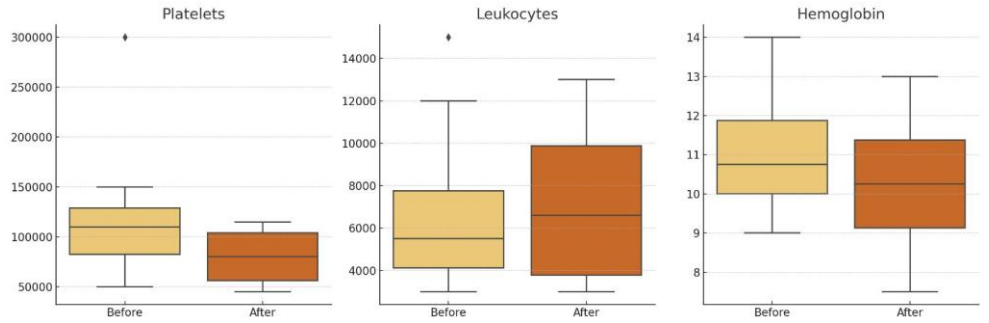

Fig. 3. Fluctuations of hematological parameters pre and post embolization

Interpretation of data based on box-plot graphs from third figure.

Thrombocytes

- distribution pre and post are hetero-

genous, but post-intervention a significant median increase is observed.
- there are extreme values (outlier), but the general trend is of **increasing.**

Leukocytes
- postintervention, median and dispersion rise significant.
- the distribution is larger, but without evident extremes - **increased systemic response** after PSE.

Hemoglobin (Hb)
- slightly, but evident increase after PSE.
- the variability is moderate, but distributions are similar; postprocedural curve is "higher"-suggesting moderate, but constant therapeutically efficiency.

TABLE II.

Essential statistical descriptive data for thrombocytes, leukocytes and hemoglobin, before and after PSE, as well as the differences between these values (Post *vs.* Pre).

	Medium level	Median	Mode	Std. Dev.	Min.	Max.	Q1	Q3
Thrombocytes, Pre	57.733,33	47.000,00	22.000,00	38.662,40	22.000,00	188.000,00	40.000,00	63.000,00
Thrombocyte, Post	95.500,00	72.000,00	56.000,00	66.639,49	38.000,00	303.000,00	56.000,00	121.500,00
Thrombocyte, Post *vs.* Pre	**37.766,67**	**25.000,00**	**34.000,00**	**27.977,09**	**16.000,00**	**115.000,00**	**16.000,00**	**58.500,00**

Thrombocytes

The mean level of platelets increased from 57.733/μL preprocedural to 95.500/μL post procedural, with a mean difference of +37.766/μL, thus indicating a substantial clinical improvement. The median increased from 47.000 la 72.000/μL, confirming an upward trend of the response. The increase is further supported by the higher Q1 and Q3 values, indicating a global distribution towards higher post-treatment values. However, the elevated standard deviation (66.639) after procedure suggested a high dispersion, possible reflecting heterogenous responses depending on the patient or on the disease severity (tab. II).

Leukocytes

The mean level of leukocytes doubled after PSE (from 3.437 to 7.775/μL), while the mean difference was +4.337/μL, showing a favorable response. Although the median has moderately increased (from 3.300 to 6.575/μL), a high dispersion is evident (SD=4.445), and the extreme post-treatment values varies between 2.600 and 16.900/ μL (tab. II).

Hemoglobin

Unlike the other parameters, hemoglobin remained at a steady state; the mean exhibited a slight increase from 10,61 g/dL la 10,91 g/dL, with a mean difference of +0,31 g/dL, considered clinically non-significant. The median doesn't change at

all (11,10 g/dL), while the quartiles had minimal modifications, indicating a hematological stability (tab. II).

Influence of gender and age over the hematological changes after PSE

There is no linear relationship between age and platelet number variation. However, older patients tend to have a reduced hematological response. The age group 50-70 years presented a more stable increasing in platelets and leukocytes level. Hemoglobin levels stayed steady, independent the age group or gender, confirming the stability of this parameter after the procedure. The differences in the increase of the platelets do not seem extremely visual between males and women (fig. 4).

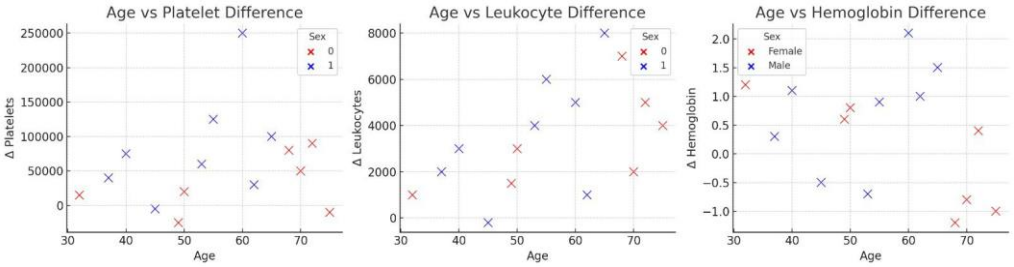

Fig. 4. Visual comparison of postprocedural response depending on age and gender

The differences between males and females regarding the hematological response post PSE are visible for thrombocytes and leukocytes, but no definitely conclusions can be made without supplementary statistical tests.

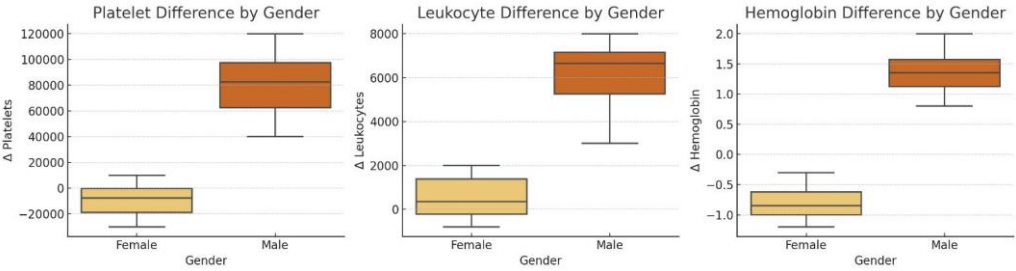

Fig. 5. Post procedural differences for thrombocytes, leukocytes and hemoglobin: females *vs.* males

TABLE III.

Summary of relevant correlations (Pearson):

Relation	Pearson Coef	Interpretation
Age-Difference Thrombocytes	-0.250	Weak negative correlation
Age-Difference Leukocytes	-0.075	No relevant correlation
Age-Difference Hemoglobin	-0.064	No relevant correlation
Sex-Difference Thrombocytes	+0.153	Weak positive correlation
Sex-Difference Leukocytes	+0.210	Weak positive correlation
Sex-Difference Hemoglobin	-0.174	Weak positive correlation

Both age and gender seemed to have only marginal influence over the post procedural fluctuations of hematological parameters in this study group. The relationships showed a weak statistical significance.

The association between the embolized splenic volume and post PSE platelet count

This analysis aims to evaluate the relationship between the embolized splenic volume and the increase in the platelet count post partial splenic embolization, in a sample of 15 patients.

The hypothesis tested is that embolizing a higher percent of spleen, the increase in thrombocytes count raised simultaneously. A simple linear regression was performed, the dependent variable was the change in platelet count post PSE, while the independent variable was the percent of embolized splenic volume. The analysis included all 15 patients (n=15).

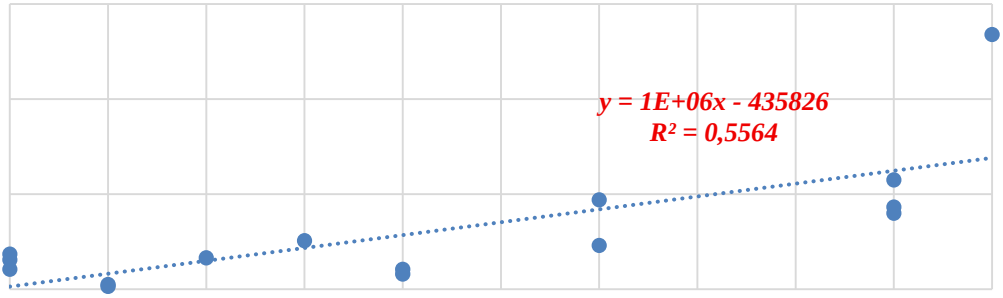

Fig. 6. Correlation between splenic infarction ratio and the platelet increase ratio after PSE

Results

The R-squared (R^2) value: 0.556 → approximately 55.6% of platelet variation could be explained through the percent of embolized volume.

The adjusted R-squared: 0.522 → adjusted for the number of observations and predictors, that indicated a moderate-strong relation.

Standard error of the estimate: 46.059,26 → indicates mean deviation of the actual values from the predicted values.

ANOVA / F Test: 16.31 / Associated p-value (F significance): 0.0014 → statistically significant

($p < 0.05$), confirming that the regression model is globally significant.

Regression Coefficients

Intercept (constant term): - 435.826 (p = 0.058) → significant negative, indicating that when the percent of embolization is zero, the model estimates a decrease of platelet level.

Coefficient for embolization percent: 1.353.123 (p = 0.0014) → significant positive, suggesting that for each unit of increasing the percent of embolization, it is estimated an increase with approximately 1.353.123 of platelet count post partial splenic embolization.

Confidence intervals (95%)

For the coefficient "percent of embolization": [629.203, 2.077.043] → the interval doesn't include the value "zero", confirming the statistical significance.

The results suggested a positive correlation and statistically significant between the percent of embolized splenic volume and the increase of platelet count after PSE. Thus, a more extensive embolization

seemed to be associated with a favorable hematological response, especially regarding the platelet count.

The survival analysis through Kaplan-Meier method in a group of 15 patients

The survival analysis is an essential tool in clinical trials for estimation of the survival rate or of the time to a relevant event (disease progression, complications). Kaplan-Meier method allows the assessment of cumulative survival probability over time, taking censored data into account. The goal of this study is to describe the survival distribution in a group of 15 patients, using data expressed in months.

Methodology

Study population: 15 patients.

Variable time is expressed in months (interval: 0-109 months).

The survival rate was analyzed using Kaplan-Meier method.

Censoring was applied to the patients who did not finish the follow-up period.

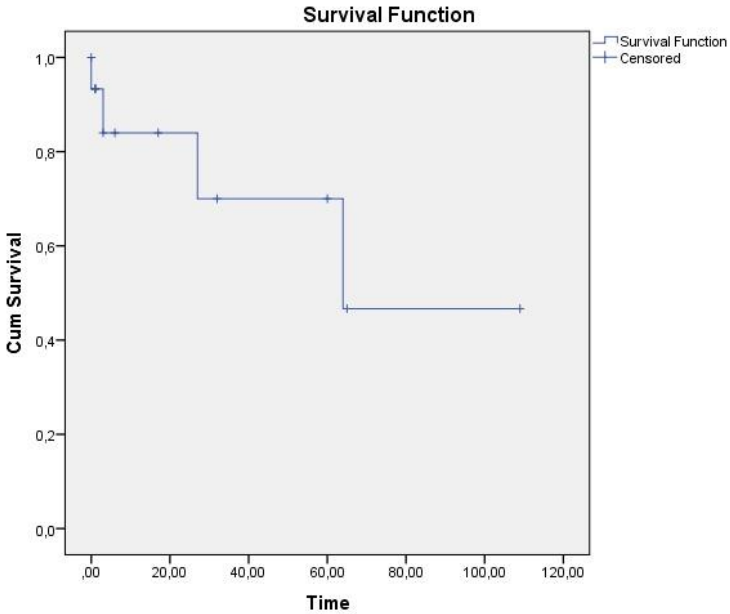

Fig. 7. The survival probability as a function of time (months)-Kaplan-Meier analysis

Kaplan-Meier graph showed a progressive decrease of cumulative survival probability on a 9-year period of time (109 months).

At 6 months, the estimated survival is approximately 73.5%.

At 64 months (over 5 years), the survival decreases to 40.8%.

The survival curve flattened out after approximately 65 months, suggesting that there are no events after this point.

Descriptive statistics

Median survival time was 64 months (confidence interval C.I. 95%: 0 – 134.1 months), indicating that 50% of patients survived at least 5 years and 4 months.

The estimated mean time of survival was 61.8 months, with a standard error of

15.04 months (C.I. 95%: 32.3 - 91.3 months).

Percentiles: percentile 50% (median): 64 months / percentile 75%: 6 months that suggests that a quarter of patients suffered an event in the first 6 months.

Survival table

The majority of events took place in the first 60 months, with only 5 events in the whole follow-up period.

After 60 months, only 3 patients remained under observation, and the curve indicated a stabilization of survival in 40% of patients.

These results demonstrated a median survival rate of over 5 years, reflecting a favorable outcome for certain patients, but also a significant risk of early events during the first month's post intervention.

The survival differences by gender: Kaplan-Meier analysis

Methodology

Study population: 15 patients.

Variable time is expressed in months (interval: 0-109 months).

Event: death or major complication

Censoring was applied to the patients who did not experience an event during the follow-up period. Patient gender: 0-females, 1-males

Statistical test for comparison: Log-Rank (Mantel-Cox)

Results

Survival estimations based on gender

Females (gender = 0):

Mean time of survival: 46.19 months (C.I. 95%: 7.34 - 85.05)

Median time of survival: 27 months (C.I. 95%: 1.18-52.81). Percentile 75%: 3 months.

Males (gender = 1):

Mean time of survival: 64.5 months (C.I. 95%: 63.81 - 65.19)

Median time of survival: 64 months (C.I. 95% unknown due to lack of sufficient events). Percentile 75%: 64 months.

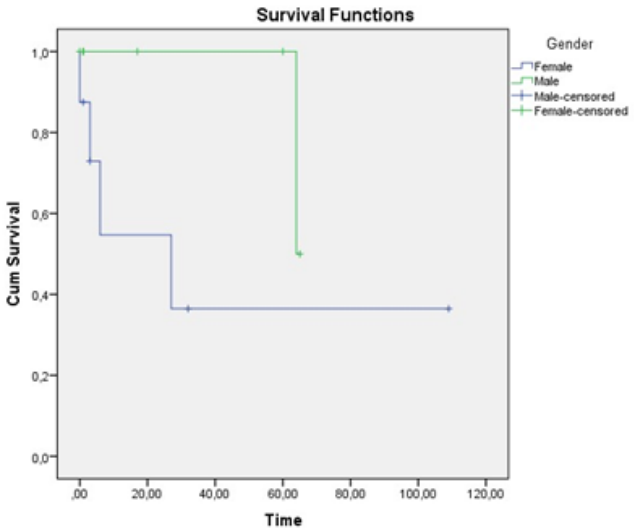

Fig. 8. Kaplan-Meier function of survival based on gender

Kaplan-Meier curve indicated a higher survival in males, with a flattened curve around 64 months and a decreased survival in females starting from the first months, with a significant reduction in the first 30 months.

Test Log-Rank. Chi-square = 1. 941 and p = 0.164 shows the difference is not statistically significant with $p < 0.05$, but suggested a possible trend in males. The results showed a clinically relevant difference but statistical non-significant regarding the survival between males and females in the study group. Males tend to have a longer survival (mean: 64.5 months *vs.* 46.2 months), with a double median comparing to that observed in females (64 *vs.* 27 months).

DISCUSSION

Splenic embolization was first introduced in early seventies by Maddison who used it for treating a refractory esophageal variceal bleeding in liver cirrhosis, and after that, the technique was improved by Spigos who imagined only a partial embolization in order to minimalize the associated complications (15, 16). Over the decades, the use of splenectomy has declined and its place has been gradually taken by this minimal invasive technique.

Our study focused on the results of PSE on hypersplenism determined by portal hypertension in liver cirrhosis. Among all the components of pancytopenia, thrombocytopenia plays a central part in cirrhotic patients. Thrombocytopenia increases a patient's risk of spontaneous bleeding, and in addition to the severity of liver dysfunction quantified through Child-Pugh classification, may contribute to make a planned surgical intervention inadvisable (18, 19). Our survey included a patient with alcoholic liver cirrhosis with severe thrombocytopenia, who was diagnosed with urothelial adenocarcinoma. Due to extremely low platelet number, the surgical intervention for associated malignancy was contraindicated. Performing PSE, the platelet level increased considerably post procedure, allowing to schedule a surgical intervention for urothelial cancer.

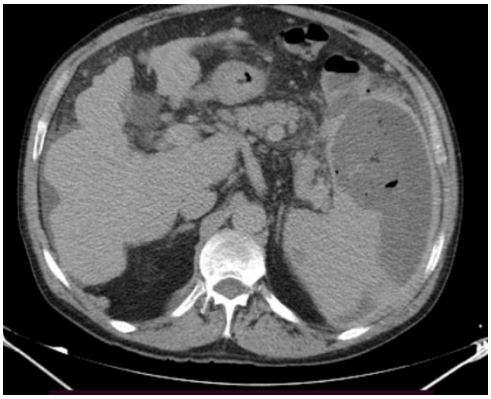

Fig. 9. Computed tomography of spleen after embolization; 50% of spleen infarcted.

Considering the case particularities, we observed different responses comparative with the whole group in two cases accompanied by autoimmune condition: either in a case with thrombotic thrombocytopenic purpura who presented a lack of response in terms of platelet increasing or a liver cirrhosis due to hepatitis C virus complicated with cryoglobulinemia, that also did not show a significant increase in thrombocyte count.

Data from literature suggested that increasing the platelet count depends on the volume of infarcted spleen which is also a predictive factor for postprocedural complications development (10, 17, 18, 19). Almost 50% of spleen needs to be infarcted to obtain a sustained increase in platelet count (20). According to the data present-

ed, we also find similar percent of infarctization in our survey (fig. 9).

Regarding the complications, we observed that postembolization syndrome consisting of fever, nausea and left upper quadrant pain was almost universal present, but without severe consequences and carefully managed with standard treatment including antibiotics. Antibiotic prophylaxis was demonstrated that it reduces the severity of complications (21, 22, 23).

Other relevant complications were acute renal failure induced by contrast medium (two patients) and splenic abscess, despite antibiotic prophylaxis. In the last case, the patient ultimately needed surgical intervention.

This analysis supported the data from literature, regarding the increase in platelet and leukocyte count which were significant, both mean and median, suggesting that the embolized spleen limited the destruction of blood cells (24, 25).

The study has several limitations: one hand the sample size is small, consisting of 15 patients, and on the other hand the study is observational and cannot demonstrate causality. Although there is a positive trend between the embolization volume and the leukocytes and hemoglobin level, the relationship with the embolization procedure is not statistically significant.

CONCLUSIONS

The findings in our survey are consistent with the data from literature regarding the improvement of hematological indices, the occurrence of complications and the relationship between embolized spleen volume and the success of the technique. Partial splenic embolization is safe when the total embolized volume does not overcome 70% of spleen volume. Periprocedural antibiotherapy is necessary in order to limit complication development. The survival rate after a period of 9 years of follow-up for a subgroup of patients remained significant due to favorable outcome of partial splenic embolization, improving the overall biological status.

CONFLICT OF INTERESTS AND FUNDING

The authors declare that there is no conflict of interest and they received no specific funding regarding this scientific research

THE ROLE OF PREDICTIVE BIOMARKERS IN THE PROGNOSIS OF DENTAL CARIES IN CHILDREN (Abstract): Dental caries (DC) in children constitutes a significant public health concern. **Aims:** to identify predictive factors associated with the development of DC in children, targeting the identification of relevant predictive models and their subsequent application in the design of personalized preventive therapy. **Materials and methods:** Our observational cohort study was conducted on a batch of 398 children. The research group (L_1) included 132 children affected by dental caries, while the control group (L_0) consisted of 266 caries-free children. Indicators of caries experience, oral hygiene status and biomarkers from oral fluid (OF) were evaluated. To identify predictive factors for the development of DC, a multivariable linear regression model (linear Mod) was constructed. The study was conducted in accordance with ethical standards. **Results:** Multivariable linear regression analysis revealed the interaction of a complex set of risk factors (elevated levels of *Streptococcus mutans* and tumor necrotic factor alpha - TNF-α) and protective factors (secretory immunoglobulin A - sIgA, transforming growth factor - TGF-β1, $25(OH)D_3$, and Ca/Pi ratio) in OF. **Conclusions:** The multivariable linear regression model exhibited strong explanatory power, underscoring the relevance of salivary biomarkers in the personalized assessment of caries risk. The incorporation of predictive biomarkers holds significant potential to improve prognostic accuracy and to optimize targeted preventive strategies for dental caries in pediatric populations across various age groups. **Keywords:** DENTAL CARIES, CHILDREN, SALIVARY BIOMARKERS, PREDICTION, PREVENTION.

INTRODUCTION

The scientific basis for caries risk assessment, prevention, and patient-specific treatment requires ongoing development, precise definition, and continuous validation (1). Caries risk assessment plays a critical role in enhancing pediatric dental care and serves as a foundational element in the design of preventive and minimally invasive treatment strategies (2). Given the preventable nature of dental caries, the early identification of cariogenic risk has become a central objective in contemporary pediatric dentistry. Predictive models incorporating clinical, behavioral, socioeconomic, and biological parameters - such as *Streptococcus mutans* (SM) and secretory immunoglobulin A (sIgA) - facilitate per-

sonalization of preventive approaches (3), selection of appropriate interventions (both non-invasive and invasive) and implementation of tailored clinical monitoring protocols (4), thereby contributing to the reduction of severe dental injuries (3).

The recent advancement of artificial intelligence and machine learning technologies has enabled the development of increasingly accurate predictive tools capable of identifying complex interactions among various risk factors (5). Predictive models are rapidly being applied to the prediction of DC in children (6, 7). However, the current precision of these models, their susceptibility to bias and their clinical applicability remain insufficiently evaluated, highlighting the need for rigorous validation and alignment with standardized methodological guidelines, in order to ensure their reliability and clinical relevance (7, 8, 9). In this context, the investigation of predictive factors for the onset of dental caries remains highly relevant, emphasizing the clinical benefits, methodological challenges and perspectives for implementation in pediatric dental practice.

Objectives. To identify predictive factors associated with the development of dental caries in children, in order to inform the construction of robust predictive models and support their integration into the design of personalized preventive strategies tailored to different pediatric age groups.

MATERIALS AND METHODS

A prospective observational cohort study was undertaken to address the objectives of this research. A total of 398 conventionally healthy children aged between 3 and 15 years were included and distributed into two proportional groups. The research group (L_1) comprised 132 children with carious lesions (33.2%, 95% CI: 29-38), while 266 caries-free children (66.8%, 95% CI: 62-71) formed the control group (L_0). The selected juvenile population was divided per age groups according to the target groups recommended by the World Health Organization (WHO) (7): 3, 6, 12 and 15 years old. Out of the total 398 children body, 98 were included in the 3 y.o. age group (24.6%, 95% CI: 20-29), 90 children in the 6 y.o. group (22.6%, 95% CI: 20-29), 102 children in the 12 y.o. group (25.6%, 95% CI: 21-30), while 108 subjects were selected for the 15 y.o. batch (27.1%, 95% CI: 23-32). The study subjects were evenly distributed by gender, with 199 girls (50.0%, 95% CI: 45-55) and 199 boys (50.0%, 95% CI: 45-55). Among all examined children, 196 (49.2%, 95% CI: 44-54) were from urban areas, while 202 children (50.8%, 95% CI: 46-56) resided in rural areas.

Data collection was carried out by applying tools in accordance with the questionnaires for assessing oral status proposed by the WHO (WHO Oral Health Questionnaire for Children, 2013) (10) and the "Chairside Guide for Caries Prevention and Management" proposed by World Dental Federation (9). The children oral hygiene status was assessed by estimating the OHI index (oral health index) according to Green and Vermillion. The level of caries experience was evaluated using the indices DMFT/dmft and DMFS/dmfs. For the early and accurate detection of carious lesions and demineralized enamel areas, the conventional clinical examination was supplemented by the use of a device based on Transillumination technology (with a 780 nm wavelength light), the *DIAGNOcam* (*KaVo Dental GmbH), following the recent algorithm proposed through the consensus*

report on clinical recommendation for caries diagnosis (11). In order to achieve a complex and personalized prediction of DC, clinical predictive factors (oral hygiene status and caries experience indices), oral immune biomarkers from oral fluid, and the results of caries risk assessment using *Cariogram Software* were analyzed (12).

For the biochemical study, OF samples were collected in the morning under fasting conditions (*à jeun*). Unstimulated OF (5 mL) was obtained from participants by passive spitting directly into sterile collection tubes, subsequently transported to the Scientific Biochemistry Laboratory of "Nicolae Testemițanu" State University of Medicine and Pharmacy.

The biochemical analysis of oral fluid included the determination of oral cavity immune biomarkers: secretory immunoglobulin A (sIgA), tumor necrosis factor-alpha (TNF-α), transforming growth factor beta-1 (TGF-β1), cathelicidin (LL-37), as well as biomarkers involved in calcium-phosphate metabolism and the mineralization of dental hard tissues: primary vitamin D_3 metabolite - $25(OH)D_3$ and the calcium-to-phosphate ratio (Ca/Pi), for all children included in the study.

To verify the reliability of DC prediction, a follow-up clinical examination was conducted after one year, including the reassessment of caries experience indices.

The study was conducted in accordance with the principles of the Declaration of Helsinki and was approved by the Research Ethics Committee of "Nicolae Testemițanu" State University of Medicine and Pharmacy.

Data were processed using the open-source software RStudio, version 2024.09.1+394 (https: //www.rstudio.com). The source code used for data preprocessing and analysis is available and can be provided upon request,

For the description of numerical variables, basic descriptive statistical analysis was applied: minimum and maximum values, arithmetic mean and standard deviation, median (Me), and interquartile range (IQR). These measures of central tendency and dispersion provided a detailed and accurate characterization of the distribution of each variable, facilitating the identification of outliers, potential skewness, and deviations from normality. To compare two independent groups in terms of quantitative variable distribution, the non-parametric Mann-Whitney-Wilcoxon test was used, due to its robustness.

For categorical variables, both absolute and relative frequencies were calculated, accompanied by 95% confidence intervals (CI) for the proportion estimates. This approach allowed for a solid statistical characterization of category-level distributions.

To evaluate the predictive factors for the occurrence of new caries one year after the initial examination, a multivariable linear regression model was constructed, including residual analysis.

Statistical analysis was performed using a conventional significance level (α) of 0.05, with Hochberg correction applied for multiple testing (*p-adjust*). The Fisher Test (F) was used to validate the predictive model.

RESULTS

The results of the assessment of the level of DC involvement are presented in first table. The caries experience indicators at the beginning of the study for the children in the research group (L_1) recorded values of 4.74 ±2.65, $p < 0.001$ for the

DMFT/dmft ± SD index and 8.06 ± 4.9, 95% CI: 7.2 - 8.9, $p < 0.001$ for the DMFS/dmfs ± SD index. The average number of demineralized enamel areas detected using the *DIAGNOcam* device was 0.77 (SD = 1.59; 95% CI: 0.50 - 1.00), $p < 0.001$. The children in the control group were free from dental caries.

TABLE I.
Values of the studied indicators in children with dental caries and in caries-free children

Variables	L_1: children affected by dental caries, n=132[1]	95% CI[2]	L_0: caries-free children, n=266[1]	95% CI[2]	Statistical Test[3]	p-value[3]	q-value[4]

The oral hygiene status of the children included in the study was assessed using the Oral Hygiene Index (OHI) by Green and Vermillion. The OHI ± SD value in children affected by DC was significantly higher (OHI = 1.57±0.63, $p < 0.001$) compared to subjects without carious lesions OHI = 0.43 ± 0.36. Hence, the oral hygiene status of subjects in group L_1 was classified as satisfactory, while that of children in group L_0 was considered good.

The complex and personalized prediction of DC using the *Cariogram Software* revealed a moderate caries risk in children with carious lesions, with the chance of avoiding new carious cavities being 53.00 (Me, IQR = 19.50), compared to caries-free children, whose chance of avoiding new carious cavities was 82.00 (Me, IQR = 18.00), indicating a low caries risk. The differences between the two groups (L_1 and L_0) recorded statistically significant values (Wilcoxon rank sum test = 3.171, $p_{adjusted} < 0.001$).

In the present study, salivary biomarkers considered by several authors (13-16) to be relevant in predicting DC were evaluated: the number of SM, and the levels of sIgA, TNF-α, TGF-β, LL-37, vitamin D_3 ($25(OH)D_3$), and the Ca/Pi ratio. Table III presents the comparative results of OF biomarker assessments in

children affected by DC (L_1, n = 132) and caries-free children (L_0, n = 266).

The number of SM in saliva was assessed in all children included in the study using the *Saliva-Check Mutans Kit (GC).* A positive test result, indicating a high SM count in saliva (> 5×10^5 CFU/mL), was observed in 53.0% of children in group L1 and in only 8.6% of subjects in group L0 ($p < 0.001$), suggesting a higher risk of developing future carious lesions for L1 subjects. A low SM count in saliva (< 5×10^5 CFU/mL), associated with a lower caries risk, was found in 47.0% of children affected by DC and in 91.4% of caries-free subjects ($p < 0.001$).

To verify the reliability of DC prediction, a follow-up clinical examination was conducted after one year to assess the indices of caries experience. Subsequently, our registrations revealed statistically significant differences between groups L_1 and L_0 for most of the indicators presented in table II. Specifically, the mean values of the variables DMFT/dmft, DMFS/dmfs, new carious lesions, and secondary caries showed a statistically significant increasing trend over time in the at-risk subjects ($p < 0.001$, $q < 0.001$). Only the number of demineralized enamel areas did not display a statistically significant difference ($p = 0.2$, $q > 0.9$). It is also noteworthy that the median distributions in the control group children remained constant at 0.00 in most cases, suggesting that only a subset of subjects develop significant changes, which supports the importance of individualized caries risk assessment.

TABLE II.

Caries experience indices in children assessed at the 1-year follow-up evaluation

1.n (%); Mean (SD), Median (IQR), Minimum Maximum, 2.CI = Confidence Interval, 3. Wilcoxon rank sum test, 4Hochberg correction for multiple testing

The obtained results demonstrate that longitudinal monitoring through repeated evaluations can reveal subtle changes or significant progressions that might be overlooked in a single-point assessment. The statistically significant differences in caries experience indicators between groups L_1 and L_0 emphasize their importance in monitoring DC. Furthermore, the use of statistical tests (Wilcoxon test and Hochberg correction) strengthens the validity of the identified differences.

The multivariable linear regression model (*linearMod*), developed to identify predictive factors for the occurrence of new caries one year after the clinical evaluation and assessment of salivary biomarkers, demonstrated a high explanatory ability. The coefficient of determination was $R^2 = 0.7724$, with an adjusted $R^2 = 0.7396$, indicating that approximately 74% of the variability in the number of new caries is explained by the set of predictors included in the model. The F-test was statistically significant ($F = 23.56$, $p < 0.001$), confirming that the model is globally valid and predictive (tab. III).

*The term (Intercept) represents the model constant (β_0), which is the mean value of the dependent variable (Y) when all predictors (independent variables) are equal to zero (or belong to the reference category in the case of categorical variables).

The results of the multivariable linear regression analysis suggest that the occurrence of new carious lesions in children is influenced by both, risk and protective factors that are clinically and biologically measurable.

I. Significant factors associated with an increase in the number of new carious lesions:

- The presence of *Streptococcus mutans* at elevated concentrations ($> 5 \times 10^5$ CFU/mL) ($\beta = 1.5283$, $p < 0.001$) proved to be the strongest predictor, associated with an average increase of 1.53 new lesions

compared to children with low SM levels.

- Oral Hygiene Index (OHI) (β = 0.4757, p = 0.002) - each 1-point increase in the oral hygiene score is associated, on average, with ~ 0.48 new carious lesions, indicating a significant impact of poor oral hygiene.
- Number of demineralized enamel areas detected with DIAGNOcam (β = 0.2486, p < 0.001) - a one-unit increase in the number of demineralized areas predicts the occurrence of approximately 0.25 new carious lesions, confirming the role of these early lesions as indicators of caries disease progression.
- TNF-α level (β = 0.0836, p = 0.002) - an increase in the concentration of this pro-inflammatory mediator is associated with a higher risk, suggesting the involvement of local inflammation in the pathogenesis of dental caries.

II. Significant factors associated with a reduction in the number of new carious lesions (protective factors):

- sIgA level (β = - 0.0073, p < 0.001) - each 1 mg/dL increase in secretory immunoglobulin A is associated with an estimated reduction of ~ 0.0073 new carious lesions, confirming the role of immune protection in caries prevention.
- TGF-β1 (β = - 0.7610, p = 0.012) - shows a substantial protective effect, suggesting a potential influence on tissue repair processes and immune response regulation.
- 25(OH)D_3 (β = - 0.0175, p < 0.001) - a strong protective factor, with adequate vitamin D_3 levels being associated with increased resistance of hard dental tissues and a reduced risk of lesion development.
- Ca/Pi ratio (β = - 2.5544, p < 0.001) - the strongest protective factor in the model, highlighting the importance of mineral balance in OF for maintaining enamel integrity.

III. Non-significant predictors (p > 0.05) :

- DMFT/dmft, DMFS/dmfs, Cariogram score, and LL-37 showed no significant associations with the development of new carious lesions, which may suggest either a limited influence in a multivariable context or a potential masking effect by other predictors included in the model.

DISCUSSION

A plethora of factors have been identified as contributing to the development of tooth decay, including but not limited to: genetic predisposition, poor health performance, malnutrition, specific dietary habits, the presence of microorganisms such as streptococci, fluoride and/or vitamin D deficiency, excessive sugar consumption or other factors such as age, gender and place of residence of children. The results of our study confirm the multifactorial nature of DC, highlighting that both clinical and biological factors significantly contribute to the development of new carious lesions. The Oral Hygiene Index (OHI) proved to be a significant predictor, which is consistent with previous studies showing a strong correlation between poor oral hygiene and increased incidence of DC (17). The number of demineralized enamel areas detected using DIAGNOcam was also positively associated with the occurrence of new lesions, confirming the importance of early identification and monitoring of incipient lesions, as emphasized in the new chairside guides for caries prevention (9) and highlighted in various studies (16, 18).

Elevated levels of TNF-α in OF proved to be a significant predictor associated with increased risk of DC, suggesting the involvement of this pro-inflammatory cytokine in the progression of the disease (16). This may be driven by the accumulation of cario-

genic dental biofilm. It has been shown that salivary TNF-α levels of children with Streptococcus mutans strains $\geq 10^5$ CFU/L, are significantly increased (19).

At the same time, elevated levels of sIgA, TGF-β1, 25(OH)D_3, and a Ca/Pi ratio >1.0 in oral fluid had a protective effect. This is supported by the literature, which highlights the immunoprotective role of sIgA (13, 14), the anti-inflammatory function of TGF-β1 (20), the role of vitamin D_3 in enamel mineralization (16, 21-23), and the relevance of the Ca/Pi ratio in maintaining the integrity of hard dental tissues (2, 16, 23).

The absence of significant associations for DMFT/dmft, DMFS/dmfs, the Cariogram score, and LL-37 suggests that, although these variables may be useful for the general assessment of dental or immune status, they did not have an independent significant influence within the applied multivariable model.

Hence, our results emphasize the need for an integrated approach to caries prevention in children, combining oral hygiene control, early detection of incipient lesions, optimization of salivary immune status, and maintenance of proper mineral balance.

Overall, the multivariable linear regression model suggests that caries risk is determined by an imbalance between microbial factors and immunological biomarkers, with major influences from *Streptococcus mutans*, the Ca/Pi ratio, and sIgA. Our findings support therefore, the integration of salivary biomarkers into a complex predictive model for caries risk assessment in children, in order to ensure higher accuracy with improved sensitivity and specificity in the prognosis of dental caries in pediatric populations.

CONCLUSIONS

The development of dental caries in children is determined by an imbalance between risk factors (elevated levels of *Streptococcus mutans* and TNF-α) and protective factors (optimal levels of sIgA, TGF-β1, 25(OH)D_3, and a Ca/Pi ratio > 1.0) present in oral fluid. The multivariable linear regression model endorsed high explanatory ability, confirming the utility of salivary biomarkers in the personalized prediction of caries risk. The integration of predictive biomarkers can enhance the accuracy of prognosis and the effectiveness of personalized strategies for dental caries prevention in children of different ages.

DIETARY PREDICTORS OF KIDNEY STONE RELAPSE AND COMPOSITION: ASSOCIATIONS WITH PASTA, MILK, AND ANIMAL PROTEIN INTAKE (Abstract): Dietary factors are known to influence the risk of nephrolithiasis recurrence, yet the specific contributions of refined carbohydrates (such as pasta), milk consumption (as a proxy for dietary calcium), and animal protein intake remain underexplored. **Materials and methods**: We analyzed data from 144 adult patients monitored between 2023 and 2025 at a clinical nutrition unit. Dietary exposures included weekly intake of pasta and milk (servings/week) and total animal protein (grams/week). The primary outcomes were lithiasis relapse (yes/no) and stone composition (calcium oxalate, uric acid, or mixed/other). Group comparisons were performed using the Mann-Whitney U or Kruskal-Wallis tests, followed by Benjamini-Hochberg False Discovery Rate (FDR) correction. Multivariate logistic regression was applied to identify independent dietary predictors of relapse and stone type, adjusting for age, sex, and residential environment. Random Forest models were used for exploratory prediction analyses. **Results**: Median pasta intake was higher among patients with relapse compared with non-relapsed individuals (1.0 vs 0.0 servings/week; $p = 0.012$). This association remained significant after FDR adjustment. Milk consumption differed significantly across stone types ($p = 0.013$; FDR-adjusted significant), with the highest values observed in calcium-oxalate stones. Animal protein intake showed a non-significant trend toward higher values in uric-acid stone formers. In multivariate analysis, pasta intake was an independent predictor of relapse, while milk and animal protein did not reach significance. The Random Forest models achieved modest predictive performance (accuracy = 0.53 for relapse; 0.68 for stone type classification). **Conclusions**: Higher pasta intake was independently associated with an increased risk of lithiasis relapse, and milk consumption differed by stone composition. These findings support the hypothesis that specific dietary patterns may influence nephrolithiasis outcomes, although the predictive value remains limited. Larger prospective studies are warranted to validate these associations and to refine personalized nutritional counselling strategies for stone prevention. **Keywords:** LITHIASIS, DIETARY FACTORS, PASTA INTAKE, MILK CONSUMPTION, ANIMAL PROTEIN, RELAPSE, KIDNEY STONES.

INTRODUCTION

Dietary and metabolic factors are recognized as crucial determinants of nephrolithiasis risk and recurrence (1-3). Despite advances in metabolic assessment and imaging, the incidence of lithiasis continues to rise globally, particularly among individuals with metabolic syndrome and type 2 diabetes mellitus (T2DM) (3, 7). This persistent increase underscores the need for a clearer understanding of modifiable nutritional contributors to stone formation.

Among dietary components, refined carbohydrates, dairy products, and animal protein have each been implicated in the complex metabolic mechanisms underlying lithogenesis (4-6, 8-11). Refined carbohydrate consumption, especially from pasta and starch-based foods, has been associated with insulin resistance, weight gain, and altered urinary excretion of calcium and oxalate (8). Conversely, milk provides dietary calcium that can reduce intestinal oxalate absorption but may simultaneously elevate urinary calcium concentrations (4, 9). High intake of animal protein contributes to an increased dietary acid load, lowering urinary pH and citrate levels while raising uric acid excretion, thereby promoting uric-acid stone formation (2, 10, 11).

However, few studies have simultaneously examined the relative contributions of these three key dietary elements—pasta, milk, and animal protein—to both lithiasis relapse and stone composition. Moreover, the available literature presents inconsistent findings, partly due to methodological heterogeneity and the limited integration of nutritional, metabolic, and predictive modeling approaches.

In this context, our study investigates the association between pasta intake, milk consumption, and animal protein intake with two major clinical outcomes: lithiasis relapse and stone composition. We further explore whether these dietary factors retain predictive value in multivariate models and in machine learning analyses. By focusing on specific, quantifiable dietary exposures within a well-characterized patient cohort, this research aims to clarify potential nutritional predictors of stone recurrence and composition, offering a basis for individualized dietary counseling and prevention strategies.

MATERIALS AND METHODS

This prospective observational study was conducted between 2023 and 2025 at a private nutrition and dietetics practice in Iași, Romania. The study enrolled patients diagnosed with obesity, type 2 diabetes mellitus (T2DM), and lithiasis, who met rigorous inclusion and exclusion criteria (12-17). All participants received detailed information about the study's objectives and procedures and provided written informed consent prior to enrollment, in accordance with ethical standards for human research. The study fully complied with the principles of the Declaration of Helsinki and received approval from the Institutional Ethics Committee (18).

Inclusion criteria required participants to be over 18 years of age, with a confirmed diagnosis of lithiasis documented through abdominal ultrasonography. Participants were also required to demonstrate the ability and willingness to attend all scheduled follow-up visits as outlined in the study protocol.

Exclusion criteria included the presence of acute complications, a current or past history of oncological disease, or contraindications to the imaging procedures used in the study (2, 19). Additional exclusion factors comprised pregnancy or breastfeeding, severe psychiatric disorders that could

interfere with protocol adherence, and refusal to participate.

Data collection involved participant screening and inclusion, obtaining informed consent, and collecting demographic and clinical information. Baseline anthropometric measurements were performed, medical documentation was reviewed, and participants completed standardized dietary behavior questionnaires (20).

The composition of kidney stones was determined by infrared spectroscopic analysis, performed at the Michel Daudon Center in Iași, which operates within the Urology Clinic of the Dr. C. I. Parhon Hospital, Iași. This method enabled precise identification of calcium oxalate, uric acid, and mixed stones, ensuring analytical consistency across all collected samples.

Statistical analysis was performed using R version 4.4.2. A significance level of $p < 0.05$ was adopted. Descriptive statistics were calculated for the cohort—means ± SD for continuous variables and counts (percentages) for categorical variables. For univariate comparisons between relapse groups, the Mann-Whitney U test was applied to continuous variables, and the Chi-square test was used for categorical variables. To compare continuous dietary variables across stone-type categories, the Kruskal-Wallis test was used.

To control for multiple testing across the dietary comparisons (three dietary factors × two outcomes), the Benjamini-Hochberg false discovery rate (FDR) procedure was applied. Multivariable logistic regression models were fitted with relapse (yes = 1, no = 0) as the dependent variable, and age, sex, urban residence (urban = 1), and the three dietary factors as independent predictors. Missing numeric values were imputed with cohort medians before regression analyses.

Secondary logistic regression models contrasted uric acid versus calcium oxalate stone composition as the outcome variable. For exploratory predictive modelling, we implemented Random Forest classifiers with stratified 70/30 train-test splits. Model performance was evaluated using overall accuracy and classification metrics computed on the held-out test set.

RESULTS

Between 2023 and 2025, a total of 867 individuals were evaluated at a private nutrition and dietetics practice in Iași, Romania, and 144 patients who met the eligibility criteria were included in the study. The mean age of participants was 52.25 ± 11.90 years. The sex distribution comprised 74 males (51.4%) and 70 females (48.6%). Regarding residence, 90 participants (62.5%) were from urban areas and 54 (37.5%) from rural areas.

Relapse status was available for 143 patients, and complete dietary information for the three factors (pasta, milk, and animal protein) was obtained for 142 patients. Complete data for both diet and relapse were available for 141 patients, as were datasets combining dietary and stone-type information.

Univariate analysis showed that patients who experienced relapse reported a higher pasta intake (median = 1.0 servings/week) compared with those without relapse (median = 0.0 servings/week), with a Mann-Whitney $p = 0.01225$.

Milk consumption did not differ significantly between relapse groups ($p= 0.32605$).

There was no significant association between animal-protein intake and relapse status: relapsed patients consumed a median of 110 g/week, whereas non-relapsed patients consumed 80 g/week (Mann-Whitney $p = 0.28031^{*}$) (tab. I).

No significant differences in demographic characteristics (age, sex, or urban versus rural residence) were observed between relapse and non-relapse groups.

Stone-composition analyses. Analysis by stone type (oxalate, uric acid, other) revealed significant variation in milk consumption, with calcium-oxalate stone formers showing the highest intake (Kruskal-Wallis p = 0.01260) (2, 9, 21).

Differences in animal-protein intake across stone-type groups approached statistical significance (p = 0.07928*), as uric-acid stone patients tended to consume more animal protein.

Pasta intake did not differ significantly between stone types (p = 0.14542*).

After applying the Benjamini-Hochberg false discovery rate (FDR) correction across the six dietary tests (three dietary factors × two outcomes), pasta consumption remained significantly associated with lithiasis relapse (adjusted p ≈ 0.0378).

Similarly, the association between milk consumption and stone type also remained significant (adjusted p ≈ 0.0378), confirming the robustness of both findings (tab. I).

Associations involving animal-protein intake lost statistical significance following FDR adjustment.

TABLE I

Univariate and multivariable analyses of dietary factors

Dietary factor	Relapse (median or trend)	P-value	Adjusted P-value (FDR)	Stone type (median or trend)	P-value	P-value (FDR)	Observations
Pasta (servings/week)	Relapse = 1.0; No relapse = 0.0	0.01225	0.0378	Oxalate = 0.5; Uric acid = 1.0; Other = 0.5	0.14542	-	Independent predictor of relapse
Milk consumption (per Serving / week)	-	0.32605	-	Higher in oxalate stones	0.01260	0.0378	Not significant for relapse
Animal protein (g/week)	Relapse = 110; No relapse = 80	0.28031	-	Oxalate = 90; Uric acid = 120; Other = 100	0.07928	-	Trend for uric acid stones, not significant after FDR

Multivariable logistic regression analyses, adjusted for age, sex, and urban residence, demonstrated that pasta consumption was an independent predictor of relapse. Neither animal protein nor milk intake were statistically significant predictors of relapse in the fully adjusted model.

A separate binary logistic regression comparing uric acid versus calcium oxalate stone composition revealed a positive association between animal protein intake and uric acid stones; however, this association lost statistical significance after application of the FDR correction (2, 10).

Additionally, the data indicated that patients with higher milk consumption tended to have elevated urinary calcium levels, which correlated with the formation of calcium-oxalate stones.

TABLE II
Predictive modeling with random forest

Outcome	Test Accuracy	Key Predictors	Observations
Relapse (binary)	0.53	Pasta intake	Model showed limited discrimination
Stone type (multiclass)	0.68	Milk intake	Moderate performance
Feature Importance	-	Pasta (relapse), Milk (stone type)	Consistent across models

The Random Forest classifiers trained with demographic and dietary information reached a 0.53 test accuracy for binary relapse prediction and 0.68 test accuracy for stone-type classification (multiclass outcome) based on the results (tab. II). The feature importance rankings showed that pasta and milk emerged as the leading predictors for their respective outcomes in both studies (7, 22).

DISCUSSION

This study demonstrates that specific eating habits-particularly pasta consumption, milk intake, and animal-protein consumption-are associated with the risk of lithiasis recurrence and stone composition. In a cohort of 144 patients, we identified a novel and statistically significant association between pasta intake and stone relapse, together with a robust relationship between milk consumption and stone composition (oxalate versus uric acid). Although animal-protein intake showed a biological tendency toward uric-acid stone development, this association did not remain statistically significant after FDR adjustment.

Our findings are consistent with the broader literature linking dietary patterns and nephrolithiasis. Dietary calcium derived from dairy products has repeatedly been shown to protect against calcium-oxalate stones in large cohorts and randomized clinical trials, primarily through intestinal binding of oxalate and the subsequent reduction in urinary oxalate excretion (4, 10, 23, 24). Therefore, the assessment and monitoring of active metabolic lithiasis must take these nutritional influences into account (12).

A high animal-protein intake is a classic risk factor for uric-acid lithiasis, increasing urinary acidity and urate excretion while reducing urinary citrate levels (2, 10, 11, 24). In our data, uric-acid stone formers tended to consume more animal protein; however, the limited sample size and semi-quantitative nature of dietary gram estimation likely reduced statistical power, leading to the loss of significance after FDR correction.

The association between pasta consumption and stone relapse represents an innovative signal of this study. Pasta, a refined carbohydrate with a high glycemic load, may contribute to lithogenesis through insulin resistance and associated changes in urinary uric acid and pH-mechanisms known to promote both uric-acid and mixed-type stone recurrence (3, 8, 13). While previous large-scale studies have investigated global dietary patterns and beverage types (25-27), very few have isolated pasta intake as an individual variable. Our findings suggest that frequent pasta consumption may serve as a proxy

marker for refined-carbohydrate, low-fiber dietary patterns associated with increased recurrence risk. Future mechanistic research should investigate whether pasta consumption directly alters urinary chemistry through metabolic effects.

The observed associations align with established biological pathways, which reinforces their physiological plausibility. Consumption of refined carbohydrates such as pasta induces postprandial hyperinsulinemia and, over time, insulin resistance, both of which influence urinary acidification and uric-acid metabolism. Milk provides calcium that binds intestinal oxalate, reducing its absorption, urinary oxalate concentration, and calcium-oxalate supersaturation (9,21). Population-based evidence further indicates that calcium-rich diets are associated with a lower recurrence risk across diverse populations (28). Conversely, animal-protein intake contributes to dietary acid load, lowering urinary citrate and increasing uric-acid excretion, thus fostering an environment conducive to uric-acid stone formation (2,10,11,24). The prevalence of oxalate lithiasis remains particularly influenced by environmental and dietary factors that modulate these metabolic pathways (2).

Our findings support the application of individualized dietary counseling in lithiasis management. Specifically, patients should be advised to (i) reduce refined-carbohydrate intake and favor low-glycemic, fiber-rich sources; (ii) obtain calcium primarily from milk and dairy products, rather than supplements consumed at inappropriate times; and (iii) moderate animal-protein intake, particularly in individuals prone to uric-acid stones. However, given the limited predictive power of diet-only models for relapse, comprehensive management should combine nutritional guidance with urinary biochemical monitoring and broader lifestyle interventions (24). Recent studies comparing type 1 and type 2 diabetic patients with nephrolithiasis underscore the necessity of tailoring management to metabolic profiles (7). Likewise, longitudinal assessments of renal function following nephrectomy highlight the long-term benefits of integrated dietary control on kidney health (17). Stone composition should therefore remain a central determinant in designing preventive and therapeutic strategies (6).

Despite the strengths of the present work, several limitations must be acknowledged. The observational and retrospective nature of the study precludes definitive causal inference and leaves room for residual confounding. The semi-quantitative dietary data introduce potential recall bias, and estimates of animal-protein intake (grams/week) may be imprecise. Although the overall cohort size provided adequate power to detect moderate associations, subgroup analyses by stone type were smaller and may have been underpowered. Finally, results from this single-cohort study may not be generalizable to populations with distinct dietary patterns, genetic backgrounds, or stone-formation rates.

CONCLUSIONS

In this cohort, pasta intake emerged as an FDR-significant correlate of stone relapse, while milk consumption was significantly associated with stone composition, showing patterns consistent with the protective physiology of calcium-oxalate stone formation. Animal-protein intake demonstrated a possible biological link with uric-

acid lithiasis, although statistical support was limited after adjustment.

Overall, these findings highlight that dietary factors alone cannot reliably predict stone recurrence, yet they identify promising avenues for further investigation into metabolic and dietary mechanisms underlying lithiasis. The results support the value of personalized nutrition counseling as an integral component of comprehensive stone-prevention strategies.

CONFLICT OF INTEREST AND FUNDING

The authors declare no conflict of interest. This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

EFFECTS OF COVID-19 ON THE DIAGNOSIS OF BRAIN METASTASES. A RETROSPECTIVE ANALYSIS (Abstract): Delays in cancer diagnosis and treatment can significantly impact patient survival and quality of life. The COVID-19 pandemic intensified these challenges by limiting access to medical services and postponing essential oncologic interventions. This study **aimed** to evaluate the effects of such delays on the diagnosis and management of brain metastases in neuro-oncology patients during the pandemic period. **Materials and methods**: A retrospective analysis was conducted on 100 patients who underwent surgical treatment for brain metastases at the Department of Neurosurgery, "Prof. Dr. Nicolae Oblu" Emergency Clinical Hospital, Iași, Romania. Patients were divided into two groups: the pre-COVID group (2018-2019, n = 57) and the COVID group (2020-2022, n = 43). Demographic, clinical, and pathological data were collected from medical records. Tumor volume, anatomical location, and histopathological characteristics were compared between groups. **Results**: The mean age of patients was 57.9 years, with a female-to-male ratio of 1.17: 1. The most common primary tumors were breast (27%), bronchopulmonary (20%), and gastrointestinal cancers (18%). Brain metastases were predominantly located in the supratentorial region (80%), especially in the parietal and occipital lobes. The median tumor volume was higher in the COVID group (16.8 cm^3) compared with the pre-COVID group (12.1 cm^3), suggesting delayed diagnosis and disease progression during the pandemic, although the difference did not reach statistical significance ($p = 0.11$). **Conclusions**: The COVID-19 pandemic contributed to diagnostic delays and increased tumor burden in patients with brain metastases, reflecting reduced access to timely healthcare. While demographic characteristics remained similar between periods, larger tumor volumes observed during the pandemic indicate that healthcare disruptions had tangible effects on disease progression. Continued research is necessary to assess the long-term impact of these delays on treatment outcomes and survival, as well as to develop adaptive strategies to ensure continuity of oncologic care during future healthcare crises. **Keywords:** COVID-19, BRAIN, METASTASES, TUMOR.

INTRODUCTION

Delays in cancer treatment can have significant implications for patient survival and quality of life. One of the most concerning consequences of such delays is the increased risk of mortality and disease

recurrence. Studies have demonstrated that timely diagnosis and early initiation of treatment are crucial for improving patient outcomes (1,2). When treatments are postponed, cancer has time to progress, which may render subsequent interventions more complex and less effective (3, 4, 5, 6). This situation underscores the importance of early interventions and close monitoring of disease progression.

Beyond biological risks, treatment delays can impose a substantial financial burden on patients. This may translate into additional long-term costs if the disease advances and requires more intensive and expensive therapies. Patients may face not only the financial strain of medical expenses but also economic losses caused by their inability to work or maintain daily activities. Thus, the consequences of delayed treatment extend beyond the medical sphere, affecting the socio-economic well-being of patients and their families.

The COVID-19 pandemic has amplified these challenges, placing significant strain on healthcare systems worldwide. Many institutions were forced to postpone elective cancer surgeries and reduce the use of systemic therapies as medical resources were reallocated to address the public health emergency. These measures have raised concerns about the long-term consequences of delayed treatment for cancer patients (2). Although it is evident that postponement negatively affected clinical outcomes, the lack of comprehensive data makes it difficult to precisely assess the impact of such delays on survival and disease progression.

Therefore, the need for high-quality data to evaluate the effects of treatment delays in oncology has become increasingly evident. Without such information, it is impossible to quantify the real impact of COVID-19 related preventive measures on cancer patients and on the healthcare systems that serve them. A deeper understanding of these effects could guide the development of more effective, patient-centered public health policies, ensuring timely interventions and optimal resource management.

Looking forward, the pandemic has served as a period of reflection for the medical community. It is essential for healthcare systems to reassess how they allocate and manage resources and to develop strategies that minimize delays in essential treatments. This requires not only better coordination among healthcare professionals but also a patient-centered approach that allows for the continuation of care even in times of crisis. Hence, future healthcare systems must be more flexible, adaptable, and better equipped to respond to emerging challenges, thereby ensuring improved outcomes for cancer patients.

In this context, our study focuses on the impact of COVID-19 in the field of neuro-oncology, emphasizing potential delays in the diagnosis of brain metastases. These metastases often present acutely, leading to new or progressive neurological deficits, symptoms of increased intracranial pressure, or seizures (7, 8, 9).

Delays in managing these conditions can have serious consequences, leading to a more severe decline in patients' health status. For example, delayed diagnosis may allow the disease to advance to a stage where therapeutic interventions become more complex and less effective, particularly in the context of heterogene-

ous molecular subtypes of brain metastases (3, 4, 5, 6). Many of these cases may require more sophisticated support and intensive management, which not only increases patient risk but also adds additional strain to the healthcare system.

During the pandemic, healthcare priorities were restructured, and resources were heavily burdened by the need to respond to the COVID-19 public health crisis. This situation led to delays in diagnosis and treatment, as well as decreased access to essential services for patients with neuro-oncological conditions. Therefore, it is crucial to analyze how these delays have affected clinical outcomes and to identify strategies for minimizing their negative impact, ensuring the efficient continuation of care.

Our study aims to provide a detailed analysis of these delays and to explore the so-called "therapeutic windows" that may arise in neuro-oncological treatment pathways. A comprehensive understanding of these aspects will not only contribute to improved management of patients in the future but will also aid in formulating more effective health policies that can meet patient needs during times of crisis. Investigating the impact of COVID-19 in neuro-oncology is essential not only for ensuring patient recovery but also for strengthening healthcare systems overall, enabling them to respond to emerging challenges with adaptable and effective solutions.

MATERIALS AND METHODS

We conducted a retrospective study of patients who underwent surgical treatment at the Department of Neurosurgery, Prof. Dr. Nicolae Oblu Emergency Clinical Hospital, Iași, Romania, during 2020-2022, and compared these findings with data from the pre-pandemic period (2018-2020).

Patients with newly diagnosed brain metastases were included, and the origin and type of primary tumors were recorded. Patients with multiple primary tumors who presented new manifestations of cerebral metastases were also included, as well as those with a syndrome of cancer of unknown primary origin.

We excluded patients with any diagnosis other than brain metastases. Patients with recurrent tumors were excluded, as were those unable to undergo MRI examination.

Patients were classified according to their access to medical care in:

- those treated during the pre-pandemic period with normal, unrestricted access (2018-2019; pre-COVID group), and
- those treated during the pandemic period with limited access to healthcare (2020-2022; COVID group).

The study analyzed 100 patients with brain metastases (57 in the pre-COVID group and 43 in the COVID group). Clinicopathological data were collected from electronic medical records and included demographic information and morphological characteristics of the cerebral metastases (location and cytopathological features).

The cytopathological examination was performed on intraoperative smears obtained from small biopsy samples collected during surgery. A small specimen (1-2 mm^3) was placed on the edge of a clean, dry, labeled glass slide and crushed gently using another labeled slide, applying sufficient pressure to spread the tissue into a

thin film on both slides. Both slides were immediately stained with 1% toluidine blue. In all cases, the cytological diagnosis confirmed the presence of brain metastases.

RESULTS

The analysis provides a detailed overview of the characteristics of patients with brain metastases included in the study, revealing valuable information about both their demographic profiles and disease progression.

A total of 100 patients were included, of whom 57 were treated before the pandemic and 43 during the COVID-19 period. This division allowed for comparison of potential differences in management and outcomes between the two periods.

The mean age of the patients was 57.9 years, with most individuals in their sixth and seventh decades of life. This suggests a higher incidence of brain metastases among middle-aged and elderly adults, consistent with the fact that such oncological complications typically occur at advanced disease stages in patients with long-standing primary malignancies. The median interval from initial cancer diagnosis to the development of brain metastases was approximately 34.42 months, indicating a substantial disease trajectory before cerebral involvement became clinically significant.

Gender distribution showed a female-to-male ratio of 1.17:1, indicating a slight predominance of women in the study population.

Regarding the patients' origin, nearly half came from rural areas (48%), while the remainder resided in urban areas (52%).

Educational level revealed a diverse profile: 62% of patients had completed secondary education, 36% held higher education degrees, and 4% had only primary education.

Overall, these data help outline a complex demographic and clinical profile of patients with brain metastases, including age, sex, education, and access to care.

The most common primary tumor was breast cancer (27%), followed by bronchopulmonary cancer (20%), and gastrointestinal tumors (18%) (fig. 1).

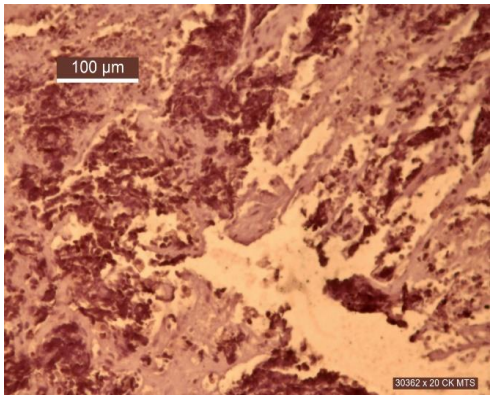

Fig. 1. Undifferentiated bronchopulmonary carcinoma metastasis.
(Immunodetection with cytokeratin, ×200)

In detail, among the gastrointestinal tumors, 5 patients were identified with esophageal cancer, 10 with colorectal cancer, 1 with pancreatic cancer, and 1 with peritoneal cancer. Other patients presented different types of malignancies: 7 were diagnosed with malignant melanoma, and 9 had renal tumors (fig. 2).

A total of eight patients were classified as having cancers of unknown primary origin. This classification was necessary because these patients died during the COVID-19 pandemic, and the cause of

death was attributed to the virus, preventing accurate determination of the tumor's primary site.

These findings highlight the diversity of primary tumors that can lead to brain metastases and provide an overview of the distribution of cancer types within this patient group (fig. 3).

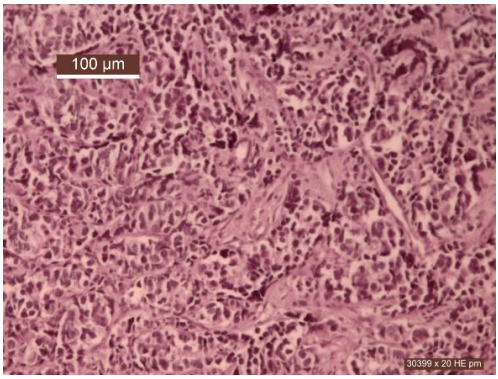

Fig. 2. Metastasis of moderately differentiated prostatic adenocarcinoma in a 68-year-old man. Preserved tubular structure is observed.

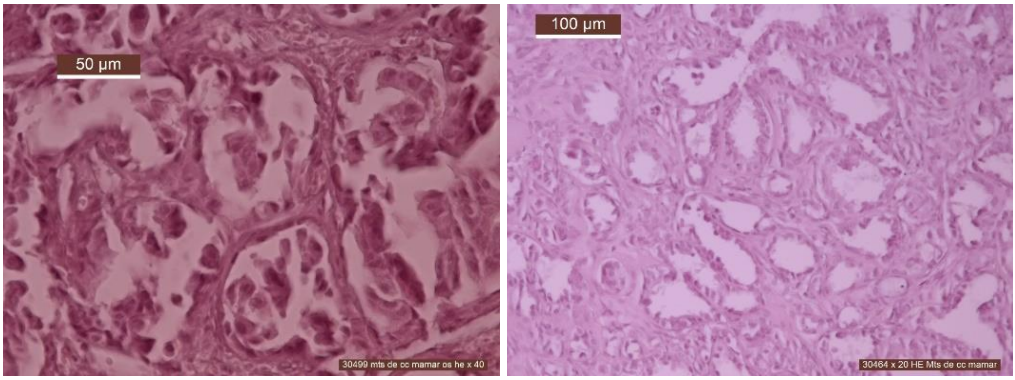

Fig. 3. Ductal carcinoma in a 60-year-old woman (HE staining, ×400). Tubular carcinoma in a 68-year-old woman (HE staining, ×200).

According to the results obtained, the distribution of brain metastases by anatomical location showed a predominance in specific brain regions. Thus, metastases were identified in the cerebellum in 20% of cases, in the right parietal lobe in 20%, in the left parietal lobe in 30%, in the right occipital lobe in 20%, and in the left occipital lobe in 10% of cases.

Regarding the distribution of brain regions, metastases were more frequently located in the supratentorial area (80%) compared with the infratentorial area (20%). This predominance in the supratentorial region is an important observation, as different areas of the brain can influence the symptomatology and clinical progression of patients with brain metastases.

These data indicate a higher tendency for metastases to localize in the parietal and occipital regions, which may have implications for treatment planning and follow-up strategies in such patients.

In this study, the majority of patients (92.6%) underwent surgical resection of brain metastases. This surgical intervention constituted an essential component of patient management, reflecting an aggressive therapeutic approach aimed at controlling metastases within the central nervous system (CNS).

From an oncological history perspective, 64% of patients had a previously diagnosed malignant neoplasm and were under regular surveillance without evidence of brain metastases before the study period. However, in 36% of patients, the brain metastasis represented the first manifestation of malignancy. These patients developed cerebral metastases without prior cancer symptoms; among them, 25 belonged to the pre-COVID group and 18 to the COVID group, suggesting a relatively balanced distribution between the two-time frames.

Analyzing the metastasis patterns, in 49% of patients the brain metastasis was the only secondary lesion identified outside the primary tumor, whereas in 51% of cases, brain metastases coexisted with metastases in other organs. This finding indicates a more aggressive systemic progression of the disease in the latter group.

The mean volume of brain metastases was 19.7 cm^3, with significant interindividual variability (±18.1 cm^3), the median being 13.5 cm^3, and ranging from 0.3 to 69.4 cm^3. When comparing the pre-COVID and COVID groups, the mean tumor volume was higher in patients treated during the pandemic, with a median of 16.8 cm^3, compared to 12.1 cm^3 in the pre-COVID period. Although this difference was not statistically significant ($p = 0.11$, Mann-Whitney U test), it may suggest a potential impact of the pandemic on early diagnosis and management of these patients.

These findings provide a complex overview of the clinical and pathological characteristics of patients with brain metastases, highlighting aspects related both to disease history and to management across different time periods (pre-COVID vs. COVID).

DISCUSSION

In malignant tumors, delayed initiation of treatment is a critical factor that significantly worsens prognosis. Studies show that even a four-week delay can have a measurable impact on morbidity and mortality among cancer patients, regardless of the treatment modality (1, 2). Such delays adversely affect all therapeutic options, though the degree of impact varies: the risk of disease progression increases by an estimated 6-8% for surgical interventions, 9% for radiotherapy, and 13% for systemic therapies such as chemotherapy and immunotherapy (1, 8, 9).

Before the COVID-19 pandemic, treatment delays in oncology were primarily determined by two categories of factors: patient-related and systemic/institutional (1, 2). Among patient-related factors, the most common obstacle was lack of financial resources, affecting approximately 28% of cases. This difficulty reflects challenges in covering the costs of treatment, transportation, and accommodation in specialized centers (3). Additional factors, such as distance from treatment facilities (12.7%), dependence on others for support (9%), and delayed presentation due to symptom neglect (16%), also contributed to treatment postponement (2, 6).

From a medical standpoint, delays of-

ten occurred when patients were initially diagnosed outside major specialized centers, where access to modern equipment and multidisciplinary teams was limited (4,7). In such cases, the time required for diagnosis and referral to an appropriate facility prolonged treatment initiation, negatively influencing prognosis and survival outcomes (3, 5).

During the COVID-19 pandemic, the impact of these factors intensified, amplifying treatment delays among oncology patients (2, 8). Pandemic restrictions including reduced treatment capacity in cancer centers, reallocation of medical resources to COVID-19 care, and isolation measures-further limited access to therapy (2, 8). As a result, delays caused by the pandemic compounded existing healthcare challenges, exacerbated the prognosis for many patients with malignant diseases (1, 2, 8).

The reduction in the number of surgical procedures and oncologic therapies, as well as the rescheduling and postponement of cancer treatments, became a global concern during the pandemic (6, 7). These disruptions affected most medical centers worldwide and interfered with supply chains, including the availability of medical personnel, which decreased by up to 79% in some institutions (6). This reduction in human resources had a major impact on hospitals' capacity to maintain standard treatment flow for oncology patients (8, 9).

However, the impact of COVID-19-related disruptions on cancer patients was not uniform. The final effect of these restrictions varied depending on multiple factors, including age, comorbidities, type of treatment required, and disease stage (5, 6). For instance, elderly patients or those with multiple comorbidities faced a higher risk of complications due to delayed care, while patients with aggressive tumors were particularly affected by postponement of essential therapies such as surgery and systemic treatments (3, 7).

These pandemic-induced changes highlighted the vulnerability of healthcare infrastructure during global crises and underscored the urgent need for adaptation strategies to ensure continuity of essential care for patients with severe conditions like cancer (1, 2, 8). The pandemic forced many oncology centers to reprioritize cases by severity and to develop innovative solutions to minimize the negative effects of restrictions on cancer patients (2, 9).

CONCLUSIONS

The present study provides relevant data on the impact of the COVID-19 pandemic on the diagnosis of brain metastases, contributing to a better understanding of how this global health crisis influenced the evolution and management of cancer cases involving the brain. Comparative analysis of patients diagnosed before and during the pandemic revealed no significant demographic differences between the two groups, suggesting that age, sex, and area of residence were not influenced by the pandemic period.

However, a statistically significant difference was observed in the median tumor volume, which was higher in patients diagnosed during the pandemic. This increase in tumor size suggests that diagnostic delays-caused by reduced access to health-care services during the pandemic-led to patients presenting with more advanced disease stages and larger brain lesions. Such situations complicate treat-

ment planning, as larger and more advanced tumors typically require more complex interventions and are associated with a less favorable prognosis.

To fully assess the long-term impact of diagnostic delays on treatment outcomes and survival among patients with brain metastases, this study will continue. The future objective is to analyze in greater detail how diagnostic delays, determined by pandemic-related constraints, affected treatment efficacy and overall disease progression.

Continuing this research will enable a more comprehensive understanding of the pandemic's consequences on oncologic care and provide valuable insights for optimizing healthcare system responses for similar crises in the future.

LAPAROSCOPIC APPROACH IN RECTAL CANCER SURGERY: A RETROSPECTIVE SINGLE-CENTER STUDY ANALYSIS OF CLINICAL OUTCOMES (Abstract): Along with total neoadjuvant therapy (TNT), surgical resection is the cornerstone of rectal cancer treatment. Minimally invasive techniques include: laparoscopic, robotic, transanal total mesorectal excision and transluminal local excision. In this study, we evaluated the feasibility and outcomes of laparoscopic surgery for rectal cancer in a single-center cohort. **Materials and methods:** We conducted a retrospective analysis of consecutive patients, who underwent surgical treatment for primary rectal cancer at a tertiary institution. A total of 99 patients were included and divided in two groups: laparoscopic (66 patients) and open (33 patients). Clinical and perioperative variables analyzed included age, sex, body mass index, comorbidities, tumor location, surgical technique, length of hospital stay, and postoperative complications. **Results:** The mean age was 68.9 years. Laparoscopy was performed in 66.7% of the patients (conversion to open resection - 15.1%) and was applicable across all age groups. Approximately half of the cases were cancers of the upper rectum. Patients underwent low anterior resection in 61.61%, 24.24% underwent abdominoperineal resection, 14.14% underwent resection with colostomy, and all cases were elective. The median length of hospital stay was 10 days in the laparoscopic group and 11 days in the open surgery group; however, no significant differences were observed between the two groups (p=0.287). According to the Clavien-Dindo classification, for the laparoscopic group, the complications were distributed as grade I (n = 12), grade II (n = 5), and grade III (n = 4); for the open group, grade I (n = 5). Anastomotic leakage (AL) was present in <10 % of cases. **Conclusions:** Rectal cancer is a complex disease that presents oncological, anatomical and functional challenges, which are addressed using a variety of surgical modalities. Our study demonstrates that the laparoscopic approach in rectal cancer is feasible regardless of age and tumor location, and showed a trend toward shorter hospital stay, the difference was not statistically significant. **Keywords:** RECTAL CANCER, LAPAROSCOPIC SURGERY, MINIMAL INVASIVE SURGERY, OPEN SURGERY, RADIOTHERAPY, LARS.

INTRODUCTION

Colorectal cancer (CRC) is the third most common malignancy worldwide. According to World Health Organization data, approximately 1.4 million new cases were reported globally in 2012, with nearly one-third arising in the rectum (1). Advanced age (≥ 80 years) is widely recognized as a major risk factor for CRC, and the growing number of older patients presents new challenges in surgical management (2). Over the past several decades, laparoscopic surgery has been increasingly adopted for the treatment of colorectal cancer and is currently recommended by guidelines (3). Compared with open surgery, laparoscopic approaches are associated with reduced surgical trauma, less postoperative pain, decreased intraoperative blood loss, faster recovery of bowel function, and shorter hospital stays (4-6). Accumulating evidence indicates that minimally invasive techniques, most notably laparoscopic and robotic surgery, achieve long-term oncologic outcomes comparable to those of open surgery. Nevertheless, questions remain regarding their influence on the technical quality of total mesorectal excision (TME) and the adequacy of oncologic clearance. Variations in reported TME specimen quality between laparoscopic and robotic approaches have been described in the literature, raising concerns about the potential implications for local recurrence and postoperative functional outcomes (7).

MATERIALS AND METHODS

This study is a retrospective observational analysis of patients who underwent surgical resection for rectal cancer at a single tertiary referral center, Sf. Ioan Emergency Hospital, Bucharest, between January 2023 and September 2025. The initial dataset included 165 patients (25 needed emergency surgery, 14 had incomplete data and 27 lost to follow up). A total of 99 consecutive patients were included in the analysis. Patients were divided into two groups according to the surgical approach: laparoscopic surgery (n = 66) and open surgery (n = 33). Ethical approval was obtained from the Ethics Committee of the St. John Emergency Hospital (Ref. No 2023-1542). Eligible patients had a histologically confirmed diagnosis of rectal adenocarcinoma and underwent elective curative-intent resection.

The choice of surgical approach was based on surgeon preference and patient-related factors. All patients were managed in accordance with the European Society for Medical Oncology (ESMO) clinical practice guidelines for colorectal cancer applicable at the time of treatment (8). Therapeutic strategies were determined on an individual basis during multidisciplinary tumor board meetings, involving colorectal surgeons, radiation oncologists, medical oncologists, pathologists, and radiologists. The indication for neoadjuvant therapy was established according to the tumor stage and radiologic assessment. Patients selected for preoperative treatment received long-course chemoradiotherapy consisting of either continuous infusion 5 of fluorouracil (5-FU) or oral capecitabine administered concurrently with pelvic radiotherapy to a total dose of 50.4 Gy. Surgical resection was typically planned within 6-10 weeks after completion of chemoradiotherapy; preventive loop ileostomy was performed in selected cases.

RESULTS

Data collection. Clinical and perioper-

ative variables were obtained from a prospectively collected institutional database dedicated to patients with CRC. Clinical, demographic and pathological data were extracted from a prospectively maintained institutional database and reviewed retrospectively. The collected variables included age, body mass index (BMI), tumor location, type of anastomosis, surgical approach, overall survival, and perioperative outcomes.

Surgical Technique. All patients underwent TME according to standardized oncologic principles. TME emphasizes complete resection of the mesorectum along the embryologic planes to minimize recurrence (11). Laparoscopic procedures were performed using a conventional multiport technique, whereas open resections were conducted via midline laparotomy. The type of anastomosis (hand-sewn, mechanical, or no anastomosis) was selected based on the tumor location and intraoperative findings. Three types of surgery were performed in our study:

- For the upper rectum: resection with anastomosis/colostomy;
- For mid-rectal resection with anastomosis/colostomy/abdomino-perineal resection (APR);
- For low rectum: resection with anastomosis (including intersphincteric resection (ISR) in selected cases) or APR.

Preventive loop ileostomy was performed in 10.10% of the patients included in the study.

Statistical analysis. The primary outcomes were perioperative and pathological results according to surgical approach. Secondary analyses evaluated the distribution of surgical approach across age groups, obesity status, tumor location, and anastomotic technique. A p-value <0.05 was considered statistically significant. Statistical analyses were performed using standard statistical software.

A total of 99 patients who underwent rectal cancer surgery were included in the analysis. The median age was 68.9 years. The proportion of laparoscopic procedures increased slightly with advancing age, accounting for 61.5% of surgeries in patients younger than 60 years and approximately 70% of procedures in patients aged 70 years or older. Obesity was another parameter studied. We noted similar proportions of non-obese (57.58% in the laparoscopic and 54.55% in the open group) *vs.* obese patients (42.42% in the laparoscopic and 45.45% in the open group) in the groups. No statistical difference was observed between the two groups ($p=0.83$). Patients' characteristics are presented in table 2. The potential relationship between type 2 diabetes mellitus and postoperative complications was evaluated. No statistically significant association was observed between diabetes status and complication occurrence ($p = 0.440$). Among patients without diabetes, 24 experienced postoperative complications, compared with five patients in the diabetic group. These findings suggest that, within this cohort, diabetes was not associated with an increased risk of postoperative morbidity. Similarly, the distribution of surgical approaches did not differ according to the diabetes status ($p = 0.99$). Laparoscopic surgery was performed in 50 non-diabetic and 16 diabetic patients, while open surgery was performed in 25 non-diabetic and 8 diabetic patients.

The median age was 71.5 years in the laparoscopic group and 69.0 years in the open surgery group. No statistically sig-

nificant difference was observed between the two cohorts (p = 0.401). These findings indicate that chronological age did not significantly influence the selection of surgical technique in this cohort, supporting the comparability of the two groups with respect to baseline demographic characteristics. Two-thirds of the patients were treated laparoscopically (66.7%). Laparoscopy was performed across all age groups, including patients aged ≥70 years. No major imbalance in distribution of obesity between the laparoscopic and open groups. Laparoscopic surgery was feasible across different age groups and body habits, including in elderly patients. We noted that age > 70 years did not preclude the use of laparoscopic surgery. For upper rectal lesions, we performed resection with anastomosis in most cases (78.7%), whereas for low rectal lesions, APR was predominantly performed (83.3%), followed by ISR (intersphincteric resection) in 4 cases (16.7%). For mid-segment lesions, resection with anastomosis was predominantly performed (71.4%). We performed anastomosis in 61.61% of the patients (tab. II).

TABLE I.

Patients'characteristics in the study

	Laparoscopic group (n=66)	**Open group (n=33)**	p
Age, years (mean=68.7)			0.8642
<60	8 (61.5%)	5 (38.5%)	
60-69	20 (62.5%)	12 (37.5%)	
70-79	31 (70.5%)	13 (29.5%)	
≥80	7 (70.0%)	3 (30.0%)	
Sex Male Female	 41 (62.12%) 25 (37.88%)	 21 (63.63%) 12 (36.37%)	0.30
Diabetes Mellitus type 2 Absent Present	 50 (66.7%) 16 (66.7%)	 25 (33.3% 8 (33.3%)	0.44
BMI category Non-obese (<30 kg/m2) Obese (>30 kg/m2)	 38 (57.58%) 28 (42.42%)	 18 (54.55%) 15 (45.45%)	0.83
LOS ≤7 days 8-14 days > 14 days	 7 (10.6%) 49 (74.24%) 10 (15.16%)	 2 (6.06%) 26 (78.78%) 5 (15.16%)	0.287

TABLE II.
Type of surgeries performed for rectal cancer in the study

Type (Rectal localization)	Upper	Mid	Low
Resection with anastomosis	37 (78.,7%)	20 (71.4%)	4 (16.7%)
Resection with colostomy	10 (21.3%)	4 (14.3%)	0 (0%)
Abdominoperineal resection (APR)	0 (0%)	4 (14.3%)	20 (83.3%)

The distribution of anastomotic technique differed according to surgical approach. Mechanical anastomosis was the most frequently performed technique overall and was more commonly associated with laparoscopic surgery (33 cases, 75.0%) compared with open surgery (11 cases, 25.0%). Similarly, hand-sewn anastomosis was performed predominantly in the laparoscopic group (12 cases) *vs.* the open group (5 cases). In contrast, non-restorative procedures were more frequently observed in the open surgery cohort, accounting for 55.3% of such cases compared with 44.7% in the laparoscopic group. This suggests a relatively higher proportion of definitive stoma procedures among patients undergoing open resection. Overall, restorative procedures were more frequently performed laparoscopically, whereas open surgery was relatively more common in cases requiring non-restorative management. However, these findings should be interpreted with caution in light of potential selection bias, as patient selection criteria - including clinical presentation, disease severity, and intraoperative findings - likely influenced both the choice of surgical approach and the type of reconstruction performed.

The median length of hospital stay was 10 days in the laparoscopic group (n = 66) and 11 days in the open surgery group (n = 33). No statistically significant differences were observed between the two approaches (p = 0.287). Patients in the laparoscopic group had a slightly shorter median hospital stay than those undergoing open surgery. No statistically significant association was observed between tumor location and the type of surgical approach (p = 0.2195). Although upper tumors were the most frequent in both groups, laparoscopic procedures were more commonly performed overall. The effect size was small (Cramer's V = 0.211), indicating a weak association.

Upper rectal cancer was predominant in both groups (45.4% for the laparoscopic group *vs.* 51.5% for the open group). Despite the lesion, our preferred surgical approach was minimally invasive (tab. III).

Early postoperative complications were related to surgery: anastomotic leakage (AL), urinary bladder necrosis, surgical site infection (SSI), and general: pneumonia and renal failure. We used the Clavien-Dindo (CD) classification (9), and the results are shown in table IV. In the laparoscopic group, the complications were distributed as grade I (n = 12), grade II (n = 5), and grade III (n = 4). In eight cases of the laparoscopic group, anastomotic leakage occurred and was treated with conservative treatment in five cases, one case benefited from radiologic drainage control, and two cases were reoperated. The overall leakage fistula rate was 8.08%. For the open group, we noted only grade I (n = 5) complications.

TABLE III.
Distribution of patients relative to anatomical segments of rectum and surgical approach

	Laparoscopic surgery	Open surgery
Upper rectum	30 (45.4%)	17 (51.5%)
Mid rectum	16 (24.2%)	12 (36.3%)
Low rectum	20 (30.4%)	4 (12.2%)

TABLE IV.
Postoperative complications

Complications after Clavien Dindo (CD) classification	Laparoscopic	Open
CD I SSI (surgical site infection) Pneumonia Renal insufficiency *Clostridium difficile* colitis	SSI - 9 (6 perineal wound) Pneumonia - 2 Renal insufficiency - 1	SSI - 2 Pneumonia - 1 *Clostridium difficile* colitis - 2
CD II Anastomotic leakage - conservative treatment	5	
CD IIIa Radiologic drainage	1	
CD IIIb Anastomotic leakage - 2 Operation Urinary bladder necrosis	AL -2 1	

Late complications were anastomotic stenosis: four cases (two in the laparoscopic and two in the open group), parastomal hernia: 2 cases, bowel obstruction: 1 case, morbidity related to colostomy: prolapse - 1 case, stenosis - 1 case, rectourethral fistula: 1 case.

DISCUSSION

This study evaluated the use of laparoscopic surgery for rectal cancer in a real-world, single-center cohort, with particular attention paid to patient age, surgical complexity, and operative decision-making. The results demonstrated that laparoscopic rectal cancer surgery was widely applied across different age groups, body habitus, and tumor locations, supporting its feasibility in routine clinical practice. Certain aspects inherent to laparoscopic surgery, such as pneumoperitoneum, prolonged operative time, and prolonged Trendelenburg positioning, may increase the risk of postoperative complications, particularly in elderly patients, who often have reduced physiological reserves compared to young-

er individuals (10). Following the successful implementation of laparoscopic techniques in colon cancer, several large multicenter randomized trials, including the COLOR II and COREAN studies, have demonstrated that laparoscopic rectal cancer surgery achieves local recurrence and disease-free survival rates comparable to those of open surgery (11, 12). Although the initial results of the ACOSOG Z6051 and ALaCaRT trials did not establish noninferiority of laparoscopy based on pathological endpoints, longer-term analyses have revealed no significant differences in two-year disease-free survival or overall survival between laparoscopic and open rectal cancer resections (13, 14).

The technical difficulties related to colorectal laparoscopic surgery are related to narrow operative field in the pelvis and limitations related to instrument mobility. Studies have shown conversion rates between 12 and 30% (15). Our data revealed a conversion rate of 15.1%. A pooled analysis of 14 randomized controlled trials reported that laparoscopic rectal resection achieved rates of positive circumferential resection margin (CRM), incomplete mesorectal excision, and positive distal margin comparable to those of open surgery, fulfilling the predefined criteria for noninferiority (16). In line with these results, the more recent LASRE trial further demonstrated comparable rates of complete mesorectal excision, negative CRM, clear distal margins, and lymph node retrieval between laparoscopic and open approaches, reinforcing the concept that minimally invasive surgery can meet established oncologic standards in rectal cancer treatment (17).

A notable finding of this study is the frequent use of laparoscopy in elderly patients. Although advanced age is often associated with increased comorbidities and reduced physiological reserve, laparoscopic surgery was performed in our study in nearly 70% of patients aged ≥ 70 years, including those aged ≥ 80 years. This suggests that chronological age alone was not considered a limiting factor for minimally invasive rectal cancer surgery in appropriately selected patients. Similar data were reported by Peltrini *et al.*, who found that age does not affect outcomes after laparoscopic rectal cancer surgery in the elderly (18). The distribution of surgical approaches according to obesity status further supports the adaptability of laparoscopic techniques. Obesity, commonly regarded as a technical challenge in rectal surgery, did not appear to significantly limit the use of laparoscopy in this cohort. Also, we did not find a significant association of obesity with postoperative complications (p=0.98). A recent meta-analysis by Gutierrez *et al.* concluded that obesity does not affect the 90-day morbidity rate or short- and long-term oncologic results in patients who underwent surgery for mid-and lower rectal cancer (19). In our study, the distribution of surgical approaches did not differ according to diabetes status (p = 1.000). The absence of a significant association in the present study may therefore reflect the relatively small sample size, the moderate prevalence of diabetes in the cohort, or effective perioperative optimization of comorbid conditions.

According to literature, protective ileostomy is usually performed in patients with high risk of AL (male sex, diabetes, neoadjuvant therapy, distance from anal verge < 5 cm) (20). We performed loop ileostomy in 10 patients and no complications related to stoma were noted. The median LOS was 10 days in the laparoscopic group and 11 days

in the open group. No significant differences were observed between the two groups (p=0.287). Although the laparoscopic cohort showed a slightly shorter median hospitalization, the difference was not significant. These findings are broadly consistent with randomized trials such as COLOR II and COREAN, which reported faster postoperative recovery parameters in laparoscopic groups, including shorter hospital stay (11, 12). Nevertheless, unlike those large controlled studies, our real-world cohort did not demonstrate a statistically significant reduction in hospitalization duration. This may reflect the relatively limited sample size, potential selection bias, or heterogeneity in patient complexity.

Regarding postoperative complications, we did not find a significant association with diabetes (p=0.439). Consequently, although diabetes was not identified as a significant predictor of complications in our analysis, larger studies are needed to better clarify its role in postoperative outcomes after rectal cancer surgery. These results differ from several reports in the literature, which suggest that diabetes may contribute to higher rates of postoperative complications, including surgical site infections, delayed wound healing, and anastomotic leakage following colorectal surgery (21). The anastomotic patterns observed in this study provide additional insight into surgical decision-making. Laparoscopic surgery was more frequently associated with restorative procedures, including both mechanical (33 cases in the laparoscopic *vs.* 11 cases in the open group) and hand-sewn anastomoses (12 cases in the laparoscopic *vs.* five cases in the open group). In contrast, open surgery was more commonly selected for non-restorative procedures, particularly in patients with low rectal tumors. The role of laparoscopy in rectal cancer surgery has been extensively debated, particularly following the initial results of randomized trials, such as ACOSOG Z6051 and ALaCaRT, which failed to demonstrate non-inferiority with respect to pathological endpoints. However, subsequent analyses have shown comparable disease-free and overall survival between laparoscopic and open surgery (13, 14). In this context, the present study adds real-world evidence supporting the continued use of laparoscopy as a viable and adaptable surgical approach. The findings of the present study reinforce the concept that laparoscopic surgery remains the foundational minimally invasive technique and should be regarded as a reference standard when evaluating newer surgical modalities.

Postoperative complications are an important aspect to be discussed. AL was present in <10% of the cases, all of which belonged to the laparoscopic group. Interestingly, only two patients needed reoperation. Treatment consisted of peritoneal lavage, drain placement near the anastomosis, and protective loop ileostomy in one case, and for the second patient it was opted for dismantling the anastomosis and end colostomy. The most frequent severe complication of rectal surgery is AL, with a reported prevalence of 2-5% (22), but there are significant variations. We did not find any cases of AL in the open group because of the small number of cases that underwent open low anterior resection and the subclinical leaks that led to late postoperative stenosis. There were four cases of anastomotic stenosis: two in the laparoscopic group and two in the open group. Our data aligns with literature (23-26).

Limitations: This study has several limitations. Its retrospective design and

relatively small sample size limit the ability to draw definitive conclusions regarding oncologic superiority or long-term outcomes. In addition, the choice of surgical approach was influenced by surgeon preference and case complexity, introducing potential selection bias. Nevertheless, this study reflects real-world practice and provides valuable insights into the feasibility of laparoscopic rectal cancer surgery in a broad patient population.

CONCLUSIONS

In this single-center retrospective cohort study, laparoscopic rectal cancer surgery was feasible across a broad range of patient ages, body habitus, and tumor locations, including elderly patients and anatomically challenging cases. Although open surgery remained more frequently selected for non-restorative procedures and low rectal tumors, laparoscopic approaches were widely applied in routine clinical practice. In appropriately selected patients and when performed by surgeons with substantial expertise, laparoscopic proctectomy appears to be a feasible operative approach that may achieve acceptable oncologic outcomes. However, given the heterogeneity of the available evidence, further confirmation through adequately powered randomized controlled trials is warranted to more clearly define the relative roles of open and minimally invasive techniques, particularly with respect to pathological quality measures and long-term survival.

CONGENITAL IDIOPATHIC TALIPES EQUINOVARUS: CURRENT CONCEPTS AND TREATMENT (Abstract). Clubfoot is a congenital malformation that has a global distribution. Despite recent advances, its etiopathogenesis still remains unknown. Although surgical treatment was preferred in the past, the actual gold standard for treatment is conservative (the Ponseti method). Nevertheless, surgery can still be an option in a small percent of cases. As clubfeet are prone to relapses, their prevention with the use of the foot abduction orthosis (FAO) is important. **Keywords**: CONGENITAL TALIPES EQUINOVARUS, CLUBFOOT, PONSETI, FOOT DEFORMITIES.

Idiopathic congenital clubfoot or talipes equinovarus is a complex, three-dimensional rigid deformity of the foot and ankle, that affects 1 in 1,000 newborns in Romania, males being affected twice as frequently as females (1). About 50% of patients have a bilateral involvement. This deformity is characterized by the presence of four pathological deviations: *varus, cavus, adductus* and *equinus*. True idiopathic clubfeet should be differentiated from syndromic clubfeet, associated with genetic syndromes (e.g. Down syndrome and Larsen syndrome), neurological diseases (spina bifida), myopathies, amniotic band syndrome or teratological malformations. A common similar but benign deformity is the postural clubfoot, a condition determined by prolonged, in utero mispositioning of the feet, which is completely or almost completely correctable at the initial examination and requires no other surgical or conservative treatment except for passive mobilization and stretching.

Many classifications have been proposed in the past, but their reproducibility wasn't satisfactory. The most frequently used classifications are the Dimeglio and the Pirani scores. Both are based on physical examination and they were found to have a good inter-observer reliability and reproducibility after an initial learning phase (2-4). The Dimeglio classification relies on grading the passive correction of the following parameters: equinus, varus,

derotation of the calcaneus-forefoot block and the adduction of the forefoot. Upon adding up the points attributed to each deformity, clubfoot can be classified in soft-soft feet (benign), soft-stiff feet (moderate), stiff-soft (severe) and stiff-stiff feet (very severe). The Pirani score, which relies on assessing six signs, evaluates and scores both the hindfoot contracture (posterior crease, empty heel, rigid equinus) and the midfoot contracture (medial crease, curvature of the lateral border, the position of the head of the talus). The final grading is obtained by adding the hindfoot and forefoot scores. As the Dimeglio score evaluates the reducibility of the foot and the Pirani score evaluates the foot aspect, they could be used at the same time when evaluating the results and monitoring the treatment (5). *The International Clubfoot Study Group* (ICFSG) score, which is more complex and measures the treatment results by scoring the morphological, functional and radiological evaluation of the feet, also proved to have a good inter-observer reliability (6, 7).

ETIOPATHOGENY

Although many theories (8-10) have been proposed so far, the etiology remains unknown. The mechanical theory, described in the past by Hippocrates, suggested that the deformity develops due to increased intrauterine pressure during development, but it is not accepted anymore as the appearance of clubfoot has been observed at 14 weeks in a uterine cavity with abundant amniotic fluid (11). The genetic component appears to be significant, as suggested by the incidence variations among different populations: 1-2: 1,000 in Caucasians and higher in Polynesians (12-14). Other theories were related to the abnormal development of connective tissue and bones (15, 16), neurological (17-19) or vascular anomalies (20). Maternal smoking (21, 22) and early amniocentesis leading to vascular disruptions (23) increase the risk for clubfoot. The pathological modifications of clubfeet have all been well described and it is beyond the purpose of this article to review them extensively. These include: the abnormal development and malposition of the foot bones; contracture and fibrosis of soft tissues (ligaments, tendons, muscles); vascular anomalies; abnormal innervations of the peroneal muscles. All of them can be present in various degrees in patients with clubfeet.

DIAGNOSIS

The ultrasonographical diagnosis of clubfoot can be established at a mean gestational age of 22 weeks (14 to 35.6) with a positive predictive value of 83%, but the accuracy rate varies in different studies and the need for karyotyping is still debated (24). At present, the diagnosis is still clinical, based on the presence of the four typical deformities: varus, equinus, adductus and cavus. The severity and rigidity of these pathological modifications vary from one patient to another. In very severe cases, the presence of a medial plantar and a posterior retrocalcaneal crease can be noted. The circumference of the calves and the length of the feet should also be noted because calf hypotrophy is always present on the affected side. Radiological evaluation was used as a preoperative and postoperative assessment method when the treatment of clubfeet was surgical. Nowadays, radiological examination is not routinely performed in newborns due to the absence of ossification of the foot bones at that age. In addition to that, Ippolito et al. (25) demon-

strated that the talocalcaneal angle, a common radiological parameter used to assess the hindfoot, was misleading in 75% of the patients which were investigated, and it didn't reflect the true relationship between the two bones. Another issue is radiation exposure of infants. Taking into consideration the fact that radiographs are performed near radiosensitive organs and that the current treatment is mainly conservative, relying mostly on palpation of the bones in the foot, after measuring the radiation dose utilized in the assessment of clubfoot, Radler et al. (26) do not recommend taking radiographs while using the Ponseti method.

TREATMENT

The goal of treatment is to correct the four deformities and to obtain a plantigrade, functional, pain-free foot that allows standing and normal walking. Many treatment methods have been used so far and they can be divided into two groups, surgical and conservative.

Although preferred in the past decades, the surgical treatment was almost completely replaced by the conservative one. However, in certain cases such as resistant forms, very stiff types of clubfeet or residual deformities, it remains the only available option. It was usually preceded by passive mobilization or stretching sessions followed or not by immobilization, to increase foot flexibility and correct as much as possible the deviations. If results were not satisfactory and there was little progress, surgical treatment was indicated. The proper age for surgery used to vary from surgeon to surgeon, depending on the age and the foot dimension. The surgical interventions used for the treatment of clubfeet can be divided into three main types: soft tissue releases, tendon transfers and bone procedures, the last ones being reserved for older children. The most frequently used were the posteromedial approach (Turco), the posterolateral approach (Metaizeau) and the circumferential approach (Cincinnati), the latter allowing an excellent visualization. The soft tissue surgery included: lengthening of the Achilles tendon, posterior capsulotomy of the ankle and release of the subtalar joint, lengthening of the flexor hallucis longus, flexor digitorum longus, tibialis posterior tendon, capsulotomy of the talonavicular joint, partial or total release of the interosseous ligament, release of the calcaneocuboid joint and calcaneofibular ligament. The extent of release used to vary among surgeons. The corrected position of the foot was thereafter temporarily maintained by some form of internal fixation, usually a Kirschner wire passed through the talonavicular joint, followed by immobilization in a cast for 6 to 12 weeks.

Since Ponseti (11) described his method, it has become the most utilized method of treatment throughout the world. It consists of two phases: the initial correction phase and the maintenance phase. The correction phase is mainly conservative and consists of weekly sessions of manipulation and immobilization of the foot to gradually correct each of the four deformities (cavus, varus, adductus and equinus). It has a mean duration of 5 to 7 weeks depending on the stiffness of the clubfoot and the doctor's experience. The cavus is the first deformity corrected by supinating the foot and applying pressure on the first metatarsal head to realign the forefoot with the hindfoot. The adductus and the varus deformity are corrected together by performing a progressive abduction, while applying counterpressure on the head of the talus. The equinus is the

last deformity to be corrected: a percutaneous Achilles tenotomy under local anesthesia is performed after the foot can be abducted more than 60º and if dorsiflexion is less than 15º-20º. The procedure is followed by immobilization in a long leg plaster cast for 3 weeks. The removal of the last plaster marks the beginning of the maintenance phase, which consists of wearing a foot abduction orthosis for the next 4 years (fulltime during the first 3 months and 14 to 16 hours a day until the age of 4-5 years). The FAO maintains the affected feet in 60˚-70º of abduction and 10º-15º of dorsiflexion. Non-compliance with wearing the FAO was found to be associated with recurrence (27). Factors associated with non-compliance or poor-compliance are: discomfort while using the brace, low educational level of parents and low family income (28).

DISCUSSION

Satisfactory results were obtained on the short term after surgical release of clubfeet (29-31), but long term follow up studies report stiff and not fully functional feet, which needed additional surgeries (32). In a 17-years follow-up study, after evaluating foot function and patients'satisfaction, Symeonidis et al. (33) concluded that even after achieving an initial successful surgical correction, residual symptoms after surgical treatment may alter walking ability and the quality of life. Ponseti's method of treatment achieves the highest correction rate in approximately 90% of the cases as reported by different Pediatric Orthopedics Centers where the method was adopted (34-37). Complications are possible with both methods of treatment. In surgically treated patients, leaving aside the surgery-related risks, the most frequent complications are: increased stiffness of the ankle, subtalar and midfoot joints, under correction or residual deformities (forefoot adduction, persisting cavus, equinus or hindfoot deformity), talar flattening and avascular necrosis of the talus, overcorrection, in toeing gait, weakness of the plantar flexors, pain and development of arthritis (38, 39). However, after the Ponseti treatment, recurrence of one of the four deformities (usually the forefoot adductus with dynamic supination) is the most frequent complication to arise and it is correlated with the inadequate use of the foot abduction orthosis (28). Conservative treatment consisting of manipulations and immobilization in long leg plaster casts followed by bracing after the deformity is corrected can usually be effective, but with growth children don't tolerate the foot abduction braces as well. Transfer of the tibialis anterior tendon to the lateral part of the foot is preferred in these cases because it maintains the corrected position and eliminates the need for bracing (40).

The thing about clubfoot is its natural tendency to recur despite successful surgical or non-surgical correction. This is can be explained by the fact that the pathological modifications and contractures are still present in the posterior and medial aspect of the calf, ankle and foot. These relapses occur until the age of four or five, and are rare afterwards, even in only partially corrected clubfeet (41). This is the main reason for the indication of wearing the FAO for the following four years of age. In a prospective study that compared surgical treatment to the Ponseti method of treatment, Halanski et al. (42) found that despite the high recurrence rate in both groups, patients treated with the Ponseti method required less interventions for the correction of the deformity and less revi-

sion surgery. Even though this method has a high initial correction rate (90%), extensive surgery will still be required in the rest of the feet which don't respond to treatment (43, 44).

CONCLUSIONS

In our opinion, even though it has been described as a congenital malformation, clubfoot should be considered a developmental disorder due to the nature of its pathological modifications and its strong tendency to relapse. After reviewing the literature and based on our experience, we recommend the Ponseti method as the first choice of treatment. If clinicians strictly respect its principles, a high correction rate can be achieved. We consider useful weekly evaluating the foot with the Pirani and Dimeglio scores during the correction phase. The importance of the FAO cannot be overemphasized and sometimes the maintenance phase proves to be more challenging than the correction phase. As noncompliance with the bracing protocol is an important factor linked to relapses, efforts should be made to improve compliance and the brace design. Despite the high initial correction rate of the Ponseti treatment, surgery will still be necessary in those feet that don't respond to treatment and in some forms of relapsed feet.

URINOMA A POTENTIAL UROLOGIC EMERGENCY (Abstract): **Aim:** A urinoma is characterized as a collection of urine outside the urinary tract as a result of disruption of the collecting system induced by a high pressure in the collecting system **Material and methods:** We reviewed the medical records of all patients with urinoma treated in the Iasi Urology Clinic between January 1, 2013 and March 1, 2017 Results**:** A total of 36 patients, (18 males and 18 females), age between 18-70 years with an average age of 51.10 years, were included. The etiology of obstruction was represented by lithiasis 29 (80.55%) cases, pelvic cancers 5 (13.88%) cases, pyelonephritis 1 (2.78%) case and trauma 1 (2.78%) case. The size of lumbar collection was between 1 cm (n=19) and 28 cm (n=1). The interval from symptom onset to presentation was: 6-10 hours - 12 (33.33%) cases; 12-24 hours - 17 (47.22%) cases, up to 5 days - 7 (19.44%) cases. The treatment was represented by the insertion of a double J stent in 29 patients, percutaneous nephrostomy in 5 (13.88%) patients. Two (5.5%) patients were treated conservatively. The post-operative evolution of patients was favorable. The ultrasound examination before discharge revealed no collection in 34 (94.44%) patients and the presence of urinoma in evident remission in 2 (5.56%) cases. Eight (22.22%) of our patients had positive urine culture with *E. coli* (n=4), *Enterococcus spp*. (n=2), *Klebsiella spp*. (n=1) and *Pseudomonas* (n=1). Six (16.66%) of our patients had infected urinoma which needed drainage of lumbar collection. **Conclusions:** Urinoma is a rare complication secondary to ureteral obstruction and it has a high risk of infection. All the cases must be investigated in hospital, double-J stent insertion and antibiotic therapy is the most frequent treatment option but some selected cases can be treated conservatively **Keywords**: URINOMA, LITHIASIS, DOUBLE-J STENT.

Urinoma is a pathological situation in which the patient presents an encapsulated collection of extravasated urine, usually located in the perirenal space but at times found in the retroperitoneal space, peritoneal cavity, pleural cavity, and even in the mediastinum (1). Urinoma is secondary to ureteral obstruction with cause a high pressure above the obstacle, but the exact mechanism is not fully understood.

The etiologies for spontaneous urinary extravasation from the upper urinary tract are: caliceal fornix extravasation and ureteral (or peripelvic) rupture. The former is caused by a sudden increase in renal pelvis pressure and backflow of urine into the

renal sinus in case of obstruction. This is considered to be a protective physiological mechanism producing decompression that may protect the kidney from high-pressure injury (1).

In patients with obstructive uropathy, there is often a sharp rise in intrapelvic pressure and the collecting system may rupture at its weakest location-the fornix. Being relatively rare, this phenomenon has not been systematically studied.

Urinomas in children are rare and secondary to obstructive uropathies, such as posterior urethral valve, pelviureteric junction, and/or vesicoureteric reflux.

The diagnosis of the urinoma, although uncommon, is important for emergency physicians because it needs a specialized urological service where to admit and to offer special treatments to the case.

The treatment of perirenal extravasation should be individualized. Conservative follow-up, endoscopic treatment, percutaneous urinary drainage, and surgical correction of obstruction have all been suggested depending on the underlying cause and amount of extravasated fluid.

MATERIAL AND METHODS

In this retrospective study, the medical records of all patients with urinoma admitted and treated in the Iași Urology Clinic between January 1, 2013 and March 1, 2017 were reviewed. Diagnosis was performed by ultrasound and fore some cases by CT scan. Data on age, presence and degree of ureterohydronephrosis (UHN), imagistic dimensions of the urinoma, etiology, time from symptom onset to presentation and treatment method were collected.

RESULTS

Between 2013-2017, 36 patients, 18 males and 18 females were diagnosed with urinoma. The age of the patients was between 18-70 years with an average age of 51.10 years. All patients had UHN, the UHN's degree was I-II (out of V) in 28 cases and III-IV in 8 patients.

TABLE I.

The etiology of obstruction was represented by lithiasis 29 (80.55%) cases, pelvic cancers 5 (13.88%) cases, pyelonephritis 1 (2.78%) case, and trauma 1 (2.78%) case (figure 1). Of this patient 17 (47.22%) had urologic history (1 stone wave lithotripsy, 6 nephrostomies and 10 ureteral stents indwell). Eight (22.22%) of our patients had positive urine culture, most encountered bacteria were *E. coli* (n=4), followed by *Enterococcus spp.* (n=2), *Klebsiella spp.* (n=1) and *Pseudomonas* (n=1). Six (16.66%) of our patients had infected urinoma which needed drainage of lumbar collection.

The interval from symptom onset to presentation was: 6-10 hours - 12 (33.33%) cases; 12-24 hours - 17 (47.22%) cases, up to 5 days - 7 (19.44) cases. The treatment was represented by the insertion of a double J stent in 29 (80.55%) patients, percutaneous nephrostomy in 5 (13.88%) patients and 2 (5.55%) patients were treated conservatively. The post-operative evolution of patients was favorable. The so-

nographic examination before discharge revealed no collection in 34 (94.44%) patients and the presence of a collection but with smaller size in 2 (5.56%) cases.

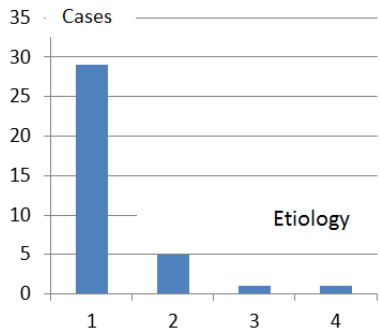

Fig. 1. Etiology of urinoma
(Legend: 1- lithiasis, 2- pelvic cancer, 3- pyelonephritis, 4- trauma)

DISCUSSION

Urolithiasis is a disease with an increased incidence and prevalence worldwide. Although rare, urinoma is one of the possible complications of urolithiasis. According to Pampana *et al.* (1) perforation could occur at any level from the calix to the bladder but it is usually seen at the fornices and upper ureter. It may lead to several serious consequences including urinoma, abscess formation, urosepsis, infection, and subsequent irreversible renal impairment. This leads to the necessity to early intervene in the presence of urinoma by performing urgent double-J stent insertion, nephrostomy tube insertion, or in some cases ureteroscopy with stone extraction.

The mean age of patients in our group was 51.10 years, which is very similar as the one of Gershman's (2) group of 108 patient which was 52.3 years. Regarding the male: female ratio in our group was 1:1but in other studies was 7:3 (2, 3).

In our study, the etiology of obstruction was represented by lithiasis (80.55%) followed by pelvic neoplasms (13.88%). Urolithiasis was also the main cause of obstruction in studies of Gershman and Almujalhem (2, 3). Rare etiologies for urinoma were also described. These include obstruction because of posterior urethral valves (5), gravid uterus (6), iatrogenic causes (7, 8), pelvic-ureteric junction (PUJ) obstruction (9), vascular extrinsic compression (10, 11), i. v. fluid administration (12), bladder carcinoma (13), retroperitoneal fibrosis, vesical-ureteric junction obstruction (2).

Most of our patients (80.55%) were evaluated in the first 24 hours of symptoms onset, but urinoma usually does not have a specific symptom, although Doehn *et al.* (14) states that one of the specific manifestations of forniceal rupture is the sudden pain relief due to the decrease in collecting system pressure. Sometimes this situation could not be differentiated from a renal colic but sometimes could mime an acute abdomen. In our study, the patients had no atipic symptoms, most of them declared lumbar pain and the first ultrasound examination diagnosed the lumbar collection.

Most of cases reported in the literature have a delayed diagnosis due to the gradual onset of symptoms, including loin pain and sepsis (when they become infected). Pain in the loin and infection are commonly thought to be the effects of pyelonephritis, and ultrasound is an appropriate first-line investigation to exclude hydro nephrosis or collections.

Contrast-enhanced CT has an increase specificity regarding diagnostic because urine flow into the fluid collection can be

documented by increased attenuation in the collection on delayed images but imaging alone is not able to distinguish between a urinoma and other types of fluid collection (15, 16).

In some cases, the diagnostic could be very difficult due to lack of symptoms. Diamond and Marshall (4) reviewed 34 patients with spontaneous urinary extravasation, and nine of these patients were treated through exploratory laparotomy for acute abdominal conditions. In this situation, imagistic evaluation of the patient is very important. According to Moak *et al.* (15) and in our case, ultrasonography represents the first line of investigation for renal colic.

The most important treatment is to deal with the underlying condition that led to the urinomas formation in the first place (16). Nephrostomy or stenting is needed in cases caused by leakage without obstruction such as in traumatic injuries or postoperative anastomotic dehiscence. If the urinoma is small, it may not need to be drained separately. The urine may reabsorb if further flow into the urinoma has been eliminated.

When obstruction of the urinary system causes the urinomas, the obstruction needs to be relieved.

Urinoma drainage is indicated in several situations. Fever or leukocytosis, suggesting that the urinoma is infected is good reason to proceed to drainage. The urinoma may need to be drained to reduce pain or pressure on adjacent structures (16).

In our study only 8 (22.22%) had positive urine cultures, most frequent bacteria were *E. coli*. This percent is high compared with results of Gershman et. al. in which case only 5.2% had a documented urinary tract infection, but lower as the percent obtained by Doehn *et al.* which was 27.4%. This author also noticed that more than half of the patients had systemic signs of

infection such as leukocytosis (54.3%) and/or elevated C-reactive protein level (61.5%).

According to Doehn *et al.* (14) urinoma is a potential urologic emergency due to the reported risk for perinephric abscess formation and urosepsis that carry high morbidity rate. The author performed in all patients, primary endoscopic therapy (internal drainage) (96.3%) or insertion of a nephrostomy tube (3.7%) and concluded that with a low-pressure system and antibiotic treatment, the outcome is excellent, and secondary complications can be effectively prevented. Therefore, minimally invasive procedures or conservative care offer excellent results, and several case reports confirm this.

We performed insertion of a double J stent in 29 (80.55%) patients, percutaneous nephrostomy in 5 (13.88%) patients with good results, taking into consideration same clinical elements (general condition, fever, risk of infection, renal function, inflammatory elements, the initial cause of UHN). No collection was revealed in 34 (94.44%) patients before discharge. The conservative treatment was applied only in 2 (5.55%) cases. In some cases, this can be an option. Kalafatis *et al.* (17) treated 35 (41%) of 81 cases in a conservative approach (bed rest, intravenous fluid, and antibiotic) and concluded that conservative management can be applied to certain patients with fornix rupture. Also, Almujalhem (3) treated conservatively 57.5% of patients and concluded that that conservative management is a valid option of treatment of noncomplicated cases of spontaneous fornix rupture.

CONCLUSIONS

In our study, we find that urinoma is a rare complication of ureteral obstruction which affect both males and females, often secondary to lithiasis and can become a potential urologic emergency, Risk of infection and evolution to abscess is high and leads to the necessity to early intervention to decompress the collecting system. Ultrasound may detect fluid collections in the perinephric or retroperitoneal areas, but is recommend contrast CT to confirm the diagnosis.

Fluid around the kidneys, ureters, or bladder may represent extravasated urine, and further imaging may be necessary to characterize injuries fully.

Double-J stent insertion is the primary endoscopic therapy with good results. Some selected cases can be treated conservatively.

UNIVERSAL AND PARTICULAR ASPECTS OF SCIENTIFIC GROWTH AND SPIRITUALITY IN THE FORMATION OF MEDICAL RESEARCHER (Abstract): The education and growth of researchers should aim not only to teach concepts but also to form character. The process of initiation into a field requires the practice of virtues explicated in the article below. This article proposes that scientists develop their character along two planes: a vertical plane that is concerned with internal moral formation of the virtues of the scientist and a horizontal plane that is concerned with societal influence and the role that medical research plays in serving humanity. We also argue that scientists that view their formation and research practices coexisting with a belief in God and faith may enlighten and embolden their research experiences and endeavors. **Keywords:** SPIRITUALITY, VIRTUES, SCIENTIFIC FORMATION, MEDICAL RESEARCH, FAITH.

"In the religious sphere, the classical expression for wholeness is 'the peace of God' which, according to St. Paul, exceeds all nous (rational understanding), and which is able to safeguard the heart (the center of personality) and the noemata (acts of rational understanding)" (1).

Yet while there exist both supporters and skeptics of this line of inquiry, current and forthcoming empirical evidence in this field published on the connection between religion and health continues to strongly indicate a positive correlation. Prestigious universities are conducting programs of research in the field and numerous top journals have published findings that are statistically significant. Therefore, we encourage new medical researchers and social science investigators to incorporate this field in their formation and familiarize themselves with this work and further build future research on evidence that have been already published in this domain. We will go a step forward and argue in this paper that a researcher's personal and professional formation will benefit from an alliance between religion and medicine-an alliance which could generate new knowledge about how faith and religion contributes to health and healing in people (2).

LIMITATIONS IN SCIENTIFIC INQUIRY

Some of the most fundamental questions of humanity such as *what is the mean-*

ing of life or *what happens after we die* remain largely overlooked by modern scientific inquiry which privileges that which is quantifiable. Such questions do not easily lend themselves to quantitative experimentation, and we must recognize that scientific research remains powerless to provide answers to these profound questions. Recognizing the limitations of the scientific mind in obtaining a complete objective grasp on reality of truth about the world and our place in it, nevertheless, the paper endeavors to comment on the motivation, values, and assumptions in scientific inquiry and biomedical research aligned with the quest for the philosophical, moral, and religious truth about the world and what place we - the scientists and/or care takers have within it. Additionally, we will expand on the possibility that the medical scientists seek the truth and could bear witness to the truth in harmony with God's created order. In this empirical reality of current world, a spiritually attuned scientist may bring God's created order more fully to light and stretch his own horizon towards the uncreated light wherein the Creator dwells.

Many top scientists view their research practices in the light of spirituality. A notable example is Francis Collins: "*I have found there is a wonderful harmony in the complementary truths of science and faith. The God of the Bible is also the God of the genome. God can be found in the cathedral or in the laboratory. By investigating God's majestic and awesome creation, science can actually be a means of worship*" (3).

Religion and spirituality impact on medical care and health are studied across the globe (4); as an integral part of the health care system researchers should be guided in their work and constantly reflect on how their research is applied to improve the society in general and the well-being of the patients. This purpose may remind the scientist that serving humanity is also an expression of serving God.

WISDOM GUIDES SCIENTIFIC RESEARCH FORMATION

It is not enough for medical science to increase general knowledge; the purpose of science is to serve the welfare of communities. While clinical research is essential, the quality of this research is reflected directly by the strengths and weaknesses of the discipline itself. As a result, the education and formation of both clinicians and researchers should be aiming not only towards teaching concepts but also to form character. We then propose the formation of such character on two planes:

A vertical plane mainly focusing on moral formation and virtues a scientist may acquire to be a good person, e.g. justice, honesty, humility, graciousness as well as cultivating the virtues expressed in serving others, e.g. kindness and love. All these criteria are very similar with those that are cultivating and nourishing a relationship with God.

A horizontal plane mainly concerned with the way how the scientist may influence the society and the services brought to the humanity. This plane certainly aims to align the research in the way that society benefits but also appropriate boundaries to scientific quest for progress and knowledge are maintained.

RESEARCH AND VIRTUES

Those responsible for training new researchers should seek to develop not only the research skills of students but also their character. Contemporary moral philosopher Alasdair MacIntyre argues that new participants in any complex social activity, such

as scientific research, must develop character-building virtues in order to learn their craft (5). Students of novices must accept the authority of established standards of excellence in research and recognize the inadequacy of their own work in light of those standards before they can gain the capacity to criticize or further develop their standards.

The process of initiation into a field requires the practice of particular virtues. New researchers require *justice* to discern what they owe to whom. They must determine, for example, how to show their gratitude to their teachers, how to treat animal subjects of research humanely, and how to compensate human subjects appropriately. They require *courage* to take the risks necessary for good research. And perhaps the most crucial virtue for researchers is *honesty*. The entire enterprise of scientific research would collapse without the commitment to a truthful sharing of results. Consequently, the scientific community levies harsh punishments on scientists who betray this trust. The virtue of *honestry* also promotes a high regard and relentless pursuit of the truth. The truthful researcher constantly seeks to expand his or her knowledge and avoids misleading sources. Such researchers candidly evaluate their own performances, and by practicing *humility*, seek out constructive criticism.

Educators must do more than discuss virtues because the virtues are not abstract intellectual concepts. Rather, they are habits of good character and behavior; students will acquire them only through active participation in research under the close guidance of mentors who possess these virtues themselves. Research from the "positive psychology" movement indicates that under the right circumstances virtues can be taught. MacIntyre's work suggests that virtuous behavior will flourish only within communities that hold the virtues at the core of their common life (6). Therefore, academic departments must recruit and promote faculty members who exemplify virtue.

This emphasis on the moral formation of researchers is meant to supplement, not replace, the existing guidelines on ethical research. Indeed, fidelity to fundamental research statutes, such as those regarding informed consent, could be considered a virtue. However, these guidelines may not always provide a clear direction in challenging situations, and from time to time institutions will promulgate the guidelines as unethical. In response, virtuous persons must act upon their character and pursue right.

A CHRISTIAN ASCETIC TRADITION AND ETHICS IN RESEARCH

We assume that a student who embraces a research career will seek a practical pathway by which the student can develop virtuous habits of character. Lessons from literature that reflect on virtues would further allow researchers to learn from the long history of ethics (e.g., authors like Homer, Aristotle, Benjamin Franklin, and Jane Austen). Several religions consider the virtues necessary for a good and moral life; thus, researchers can enrich their understanding of the virtues by engaging with these traditions and welcoming religious perspectives in discussions about research ethics. This so called "open pluralism" can contribute to the professional development of novice researchers, particularly if they belong to one of these religious traditions (7).

To illustrate we will offer a few considerations from the ascetic tradition of the Near East. In the Platonic model of psychology, the human psyche consists of three key elements: the noetic, or intellect;

the incentive describing desires and animations; and the appetitive, the ability to satisfy bodily needs. Each element can be characterized by the virtues of justice, courage, and temperance respectively, with wisdom as the overruling principle of the human soul. A modern commentator of Christian-Platonic understanding, John Claude Larchet builds on the philosophies of early Christian thinkers such as St. John of Damascus and Maximus The Confessor. Larchet describes these powers of the human soul as vegetative (nutrition and growth), animal (aggressiveness, desire and affectivity) and reasoning (reason being the principal characteristic and that distinguishes humans from all other creatures) (8).

The power of reasoning has two important faculties: the spiritual faculty (intellect, or nous, linked to humans' noetic ability and responsible for the moral and psychological senses of consciousness) and the faculty of self - determination (8). Although it adopts the Platonic virtues, the Christian ascetic tradition, with respect to the incentive element of the soul, focuses on the virtue of love, cultivating practices that exhibit brotherly love and compassion (9). Early Christian-Platonist thinker, St. John Damascus, described the contrasting "sins" to the incentive element as including "heartlessness, hatred and lack of compassion" (10). Peter of Damaskos states that love of neighbor is highest among all virtues (11). And St. Isaac of Syria states that a person whose incentive powers are in the right order has a heart "burning with love towards the whole creation: towards men, birds, animals, demons and every creature…cannot bear to hear or see the least harm done to or misfortune suffered by creation" (12, 13). In contrast, the "passions" are barriers to manifesting love. The passions should not be understood as human emotions but rather as vices precluding obedience to the Word of God (14, 15). Examples of these passions include avarice, bitterness, resentfulness, anger, pride, jealousy, lustfulness, or what the ascetic fathers call "self-love." The Church teaches that such "passionate" persons will be preoccupied with satisfying their own desires for pleasure, wealth, and praise, and will fail to attend to or to cultivate the true virtues of compassion and mercy. Particularly relevant to research practice, those who give in to their passions will regard others as rivals or as impediments towards satisfying their self-love (9) - a pattern that is likely to erode the spirit of teamwork and undermine a research team's effectiveness and success.

An important reason for bringing to light these traditional thinkers in contemporary practice and regarding the ethical growth of researchers and scientists is that we believe a similar model can be used as an impetus towards understanding the purpose and virtuosity of performing scientific research.

UNDERSTANDING SKILLS AND WISDOM

There is a distinction between two types of knowledge - wisdom and skill- that applies to every realm of life including medical research. In this section, we will discuss the distinction between phronesis, or practical wisdom, and techne, or technical skill, as used in Aristotle's language. Phronesis is the development or internal formation of the self as someone cognizant of his or her purpose that acts with wisdom in all areas of life; techne is the production or formation of an outside object or external good (e.g., a drug, a car, a hospital). Phronesis aims at moral and ethical understanding and virtuous living, whereas techne aims at the creation of virtuous products (16).

Those who teach medical sciences or research techniques should exhibit "tech-

nical" knowledge, the product of their teachings being the skills that are imparted on their students. Teachers should further develop practical wisdom by applying and practicing virtuous behavior in their own lives so they can become role models for their students.

WISDOM - A COMMON GROUND FOR SCIENCE AND RELIGION

Since antiquity wisdom has been understood as a psychological trait. In modern times, wisdom has been variously described as involving social attitudes or behaviors, pragmatic knowledge of life, emotional homeostasis, reflection or self-understanding, value relativism and tolerance, and the acknowledgment of uncertainty with the ability to cope with it effectively. Although broadly defined, wisdom is consistently recognized as including thoughtful decision-making, compassion, altruism, and insight (17). In ancient philosophy, by contrast, wisdom was considered attainable in the context of practicing "askesis," which implies exercises of self-control, self-discipline, self-denial, and meditation guided by a mentor. Both Western and Eastern religions teach that to develop wisdom one needs to practice this self-constraint, disciplined morality, charitable concern, and compassionate actions (17).

According to Pavel Florensky, a Russian Orthodox theologian and thinker, wisdom is Divine and a direct representation of God's creative love. "Sophia is the original nature of creation, God's creative love… For everything exists truly only insofar as it communes with the God of Love, the Source of being and truth" (18). Because of this act of love, wisdom is imprinted in each one of us "in our hearts by the Holy Spirit which is given unto us' (Romans 5:5)". The medical arts seek to integrate science with this wisdom from the Holy Spirit for the benefit of patients. The purpose may not always be to cure but to help the patient throughout the process, while instilling a realistic hope or peace in individual suffering, something medical science alone cannot do. Medical disciplines therefore serve a greater purpose: to understand needs and sufferings of patients and address these problems through medical practice and research. We suggest that the training of practitioners and researchers therefore needs to address both developments of self as well as sensitivity to others.

CONCLUSIONS

As we have noted, religion and spirituality may enter the medical research sphere when researchers personally see their work as part of a Divine calling. The individual may view medical research as part of an obligation to serve humanity and thereby indirectly attain Divine grace. A researcher may decide to work towards ameliorating a disease, or works to serve an underprivileged community. These sorts of research endeavors encompass a drive to choose research endeavors prudently to bring about maximal scientific benefit, but which also contain an element of Divine service.

A medical researcher who is motivated by religious concerns may also strive to focus his activities upon a more vertical plane whereby he works to develop within himself the sort of moral character that is pleasing to God and other humans. He may, for example, practice prayers that help him stay regarding God and through that connection instill virtuous behaviors and thereby be a better servant of God.

These two dimensions *horizontal* and *vertical* that involves the formation of the researcher and we have highlighted in the beginning of this chapter are often pursued simultaneously and there may be places for

overlap. A case example is a researcher who employs his skills to introduce virtues into the medical education curricula and thereby affects physician behaviors and patient care. Another example is a researcher who examines the ways in which religion impacts patient behaviors and works to develop healthcare systems that serve the religious and spiritual needs of patients, clinicians, and researchers alike.

The content presented on this paper may enable the future researcher to render a deeper consideration of the idea that a fundamental relationship exists between rigorous scientific growth and spirituality, and to encourage further reflection and meditation on the universal and particular aspects of this perspective.

AKNOWLEDGEMENTS

We thank Dr. Farr Curlin at Duke University for reviewing an earlier version of the manuscript and making many helpful suggestions.

DEMENTIA-ETHICAL AND LEGAL IMPLICATIONS IN PSYCHIATRIC MEDICAL ASSISTANCE (CASE REPORT) (Abstract)*:* In psychiatric pathology, patients suffering from dementia are part of the vulnerable population category. The Universal Declaration of Human Rights and the law of mental health and psychiatric disordered patient's protection brings new changes for patients that temporarily lack decisional ability, by adding the notion of conventional representative. The purpose of this research paper is to present and evaluate the necessity of conventional representation, in the case of a patient diagnosed with medium-severe stage mixed dementia. This case is representative of the many cases of dementia in clinical practice that raises many ethical and legal discussions, and for which the conventional representation may be a solution. **Keywords*:*** INFORMED CONSENT, CONVENTIONAL REPRESENTATIVE, DEMENTIA.

Dementia constitutes a class of neurodegenerative disorders characterized by persistent and progressive alteration of cognitive functions, ascending to disability and premature death. The most common cognitive functions affected in dementia are memory, attention, orientation, language, thinking and judgment (1).

Due to this impairment of the ability of logical thinking and understanding of the patient with dementia, especially in the early stages of medium and severe illness, the question is whether to fully inform the patient about the necessary investigations required for diagnosis, the application of therapeutic methods and about performing the medical interventions necessary for restoring personal autonomy. In this situation, a person with difficulties in assessing the consequences of a decision that impacts himself can benefit from the assistance of a legal or conventional representative, that can provide a valid, informed and documented consent. Conventional representatives are people with full legal capacity, designated by the patient, that have the full legal and mental capacity to assist the patient and to represent him during medical treatment.

The legal representation will be achieved through the signing of an agreement by the patient – following a model made available by the health unit, under conditions that follow the law.

If the hospitalized person was declared as lacking decisional capacity, it will have the support of the legal representative, appointed according to law. If the patient

does not have a legal representative or has not appointed a conventional representative due to lack of mental capacity, the health unit is obliged to immediately notify the guardianship authority to establish protection measures (4-6).

CASE REPORT

The case presented below relate to patient of 58-years-old, male, from a rural area, grade 3 medically retired, having secondary education, married.

Patient presents to a doctor's office, at the "Socola" Institute of Psychiatry, in Iasi, with her daughter, with symptoms manifested by partial space-time and auto and allo-psychically disorientation, bradypsychia, psycho-cognitive slowness, episodes of confusion and anxiety, hypo-amnesic fixation and evocation, spontaneous and voluntary hypoprosexia, depressed mood, psycho-emotional lability, tearfulness.

The doctor communicated to the patient and its accompanying daughter the need for hospitalization for diagnosis and treatment plan. He presents and explains, in clear language, comprehensible to the patient, the elements of informed consent, that the patient accepts by signing the consent to admission to the "Socola" Institute of Psychiatry in Iaşi.

General history

From the patient's statements, his mother deceased at 70-years-old, showing elements of dementia syndrome (space-time disorientation, stopped recognizing family members) in the later years of her life.

Chest effort angina. Myocardial stroke, chronic stage. Stage II, grade 3 essential arterial high blood pressure, high additional risk. Grade II obesity. L4-L5 operated herniated disc. Headache syndrome. Vertiginous syndrome.

Lives at home, with his wife, non-smoking, denies alcohol consumption.

Disease history

The patient first presented at the "Socola" Institute of Psychiatry in Iasi, in 2011, for depressive symptoms, manifested by depressive mood, demobilizing ideations, pessimistic, bradypsychia, bradyphrasia, bradykinesia and mixed insomnia. At that moment, he was showing a slight cognitive deterioration (MMSE=26 points). Given the symptoms, the patient receives antidepressant treatment, with neurotrophic and neuroprotective medication.

Subsequently, he is overseen through the territorial network of psychiatry, his condition being relatively good and stable. Approximately 6 months ago, the depressive symptoms began to reappear, alongside with a dementia syndrome (partial space-time disorientation, attention and memory deficits bradypsychia, paraphrasia, dyspraxia), due to which the patient presents himself, along his family, at the hospital, for clinical and therapeutic reevaluation.

Clinical and psychiatric examination

Good general condition, grade II obesity (BMI=36 kg/m^2), abdomen increased volume due to fat tissue, lumbar postoperative scar (L4-L5).

Psycho-diagnosis of expression. The patient has a cooperative attitude, hypomobile mimicry, reduced gesturing, depressive facial aspect, wrinkled forehead, omega-melancholic, lowered mouth commissures, mobile sight, intermissive eye contact with the doctor, feels the need to frequently gaze back to his daughter to receive help answering the questions or for confirmation ("the turn-head-back sign"),

low tone and intensity voice, clothing care and proper hygiene.

Cognitive functions. The patient presents hyperesthesia, with irritability and reduced tolerance to frustration, without perception disorders such as hallucinations during the examination. Attention reveals spontaneous and voluntary hypoprosexia, difficulties in focusing and evoking (incomplete auto-biography data such as "I don't remember where I had been working". "I don't know if I took my treatment" and "I don't know why I came here"). Thought reveals ideation and verbal slowness (bradypsychia), with episodes of confusion, decreased ability to abstraction, generalization and reasoning, decreased decisional capacity, impoverished thinking, auto-depreciative and demobilizing ideation, feelings of hopelessness. Low levels of imagination.

Affective and motivational functions. The patient manifests a depressive mood, tearfulness psycho-emotional lability, generalized anxiety, physical and mental asthenia, fatigue, anhedonia, apathy. Instincts highlight eating instinct disorders, with its reduction, sexual instinct disorders with decreased libido and an exaggerated defense instinct, manifested through the fear of disease.

Effector functions. His volition is manifested through hypobulia, with lack of initiative and capacity to act. Communication is difficult, with paraphrasia, answers questions with difficulty (due to the difficulty in remembering certain information). Verbal language disorders are present, such as dysphasia with verbal amnesia and paraphrasia. Motoric conduct reveals hypokinesia with slowness and episodes of psychomotor restlessness, bradykinesia. The patient presents hypnic disorders such as mixed type insomnias.

Synthesis functions. The patient is partially space-time oriented, auto and allopsychic, disease awareness is partially present, presents derealisation, depersonalization.

Psychological evaluation. Moderate psycho-cognitive deteriorative configuration with depressive manifestation in psycho-somatic and pre-involute context. MMSE=15 points (orientation –6 points, fixation memory–2 points (4 points after rehearsals), calculus=0 points, language=6 points).

Clinical explorations

Neurological examination conducted by the neurologist in the psychiatric hospital finds an intermittent L5 radicular syndrome (possibly remaining after surgery for L4-L5 disc herniation in 2013) and raises the suspicion of lacunar cortex and vascular dementia, a reason for which he calls for a CT examination. Treatment recommendations from the neurologist were: Actovegin 200 mg x 3/day, Milgamma N 1 capsule x 3/day, Cerebrolysine 10 ml 1 vial/day, 10 days, Aflanil 100 mg 1 capsule x 2/day.

Native CT examination performed in axial plain reveals: Cortical-subcortical cerebral atrophy, predominantly supratentorial. Stage 1 leukoaraiosis, ASC predominantly in the internal carotid system. Rare cerebral ischemic gaps are present. It also highlights the thickening of the mucosa in all levels of aerial paranasal sinuses. The procedure shows a mucosa polyp in the left maxillary sinus, with a diameter of approximatively 19 mm, for which an ENT consult is recommended.

The electrocardiogram recorded a sinus rhythm with a pulse rate of 83 bpm, a blood pressure of 130/90 mmHg and sequelae of lower myocardial infarction (of which the patient claims he suffered in 2011 – did not

submit supporting documents).

Blood and urine samples didn't highlight pathological changes.

Internal medicine examination established the following diagnoses: Painful chronic ischemic heart disease; Effort chest angina; Lower myocardial infarction in chronic stage; Grade II obesity; Stage 2, grade 3 arterial high blood pressure with additional risk; Cerebral hypo-perfusion in the ascendant basilar-vertebra system. Therapeutic recommendation was: Aspenter 74 mg/day, Noliprel 1 capsule/day, Nitromint 2.6 mg 2 capsules/day.

THE POSITIVE DIAGNOSIS

The positive diagnosis determined after the clinical examination and complementary investigations is: Severe dementia in medium-severe stage. This diagnosis is supported by both ICD-10 criteria as well as DSM IV.

ICD-10 criteria

Diagnosis is based on the presence of dementia (decline in memory and thinking that compromise personal activity). Memory deterioration typically affects recording, storage and playback of new information and is accompanied by a deterioration in thinking, reasoning and reduced ideation flow, spontaneous and voluntary hypoprosexia, consciousness is retained for at least 6 months. Impaired cognitive functions are usually unequally present with: memory loss, intellectual deterioration and neurological focal signs. Judgement and understanding can be relatively well kept. Associated features: hypertension, carotidal murmur, emotional lability with transitory depressive mood, explosive crying or laughter, transitory episodes of consciousness dizziness or transitory delirium. Personality is relatively unmodified or apathy or disinhibition changes may occur, increasing previous features such as: eccentricity, paranoid attitude and irritability (2).

DSM IV criteria

A. Multiple cognitive deficits, with manifestations in both sections below:

1. Memory deterioration (impairment of the ability to learn a new information or to recall a previously learned information);

2. One or more of the following cognitive disturbances:

- Aphasia (language disturbance);
- Apraxia (deterioration of the capacity to perform motor activities, despite the sensorial function being intact);
- Agnosia (inability to recognize or identify objects, despite the sensorial function being intact);
- Disturbance in the execution function (planning, organizing, sequencing, abstracting).

B. Cognitive deficits from A1 and A2 criteria both cause a significant deterioration in social and professional functioning and represent a significant decline from the previous level of functioning.

C. Neurological focal signs and symptoms (ROT exaggeration, pseudo-bulbar paralysis, walking abnormalities, decrease of muscular strength in an extremity) or laboratory data that indicate cerebral-vascular disease (multiple infarcts involving the cortex and underlying white matter), of which it is etiologically connected with the disorder.

D. The deficits do not occur exclusively during delirium (3).

TREATMENT

From 2011 to date (patient initially diagnosed with depressive disorder) he received the following treatment: Tianeptine

12.5 mg 3 capsules/day, Alprazolam 0.25 mg 2 capsules/day, Clonazepam 2 mg/day, Nicergoline 30 mg/day, MagneB6 3 capsules/day and regular cures with Cerebrolysine vial 5 mL, 1 vial/day, 10 days per month. During the hospitalization in 2016, in addition to the anti-depressant treatment, an anti-dementia therapy is initiated with Rivastigmina patch 5 mg/day. This treatment was increased after a month to 9.5 mg/day and Memantine 5 mg/day. Medication is increased step by step, with 5 mg/week until it reached 20 mg/day. Remaining are therapeutic schemas recommended by the neurologist and internist respectively, as previously mentioned.

The patient is referred for hospitalization and monitoring in the territorial psychiatry network where he belongs, recommending continuing the treatment initiated in the hospital, returning to hospitalization if necessary, as well as the beginning of procedures to establish social protective measures of which the patient benefits given the affection of personal, social and professional functioning (GAFS=28).

EVOLUTION AND PROGNOSIS

Negative prognosis factors, in this case, are: family history (mother with dementia syndrome), debut at a relatively young age (55-58-years-old), associated somatic affections (myocardial infarction, hypertension, ischemic heart disease, obesity, brain atrophy) and a relatively rapid evolution. Positive prognosis factors are represented by family involvement and support, appropriate treatment of the associated diseases as well as a good socio-economic condition.

The evolution of this case will largely depend on anti-dementia treatment which initially appears to be satisfactory, an improvement in cognitive functions and general mental state of the patient being observed during hospitalization. Generally, the evolution of patients with dementia receiving treatment is relatively stable or slowly progressive.

DISCUSSION

This case represents one of multiple cases of dementia that question the validity of informed consent to be hospitalized in a medical institution for evaluation and treatment. The dilemma that arises in this situation is if the patient with moderate-severe cognitive deterioration has the capacity to make the right choices, to participate in the process of evaluation and diagnosis communication and to accept subsequent therapeutic conduct at any time during these stages. For many patients with moderate stage dementia (MMSE=12-15), especially those with a vascular component, a variability in cognitive symptoms exists, which makes these patients to have a fluctuating decisional capacity. When this ability is integral, the patient can appoint a conventional representative that will assist him during hospitalization, informing him clearly about the legal limits of this representation.

In our case, the patient signed the informed consent, at under the law admission, without assigning a conventional representative. During hospitalization, the patient had numerous episodes of confusion with a decrease in abstraction, generalization and reasoning capacity and a reduction in decisional capacity, moments during which the patient was assisted and supported by his daughter, without bringing into discussion the signing of the conventional model to appoint his daughter as his representative. After approximately 10 days after admission, the patient stopped experiencing these episodes of confusion, com-

pletely regaining his decisional capacity. This is a typical case in which appointing a legal representative would have been useful by allowing the family to legally intervene on necessary decisions to be taken during hospitalization, in the patient's moments of confusion.

The new rules for implementing the law of mental health and protection of mentally disordered people, approved by Order No. 488/2016, entered force on May 4th, 2016, create the legal framework for the appointment of a conventional representative. Therefore, Annex 5 of the mentioned rules contains the model of the convention for these cases, clearly establishing the rights and obligations of both parties. This representation is done free of charge. The duration of the convention is agreed by both parties and both the representative and the person represented can unilaterally terminate it.

CONCLUSIONS

Thus, starting from this case report and given these new regulations, it is recommended to more carefully evaluate the decisional capacity of the patient, both during admission as well as its likelihood of evolution during hospitalization. Taking the example of our patient situation, in the cases where there is a suspicion of deterioration of the decisional capacity, besides informed consent, patients are informed of the possibility to appoint a conventional representative and they are presented with the conventional model of the present rules. By signing the informed consent and the agreement to appoint a conventional representative, the patient is protected and given the insurance that his wishes are respected, even in times of decisional incapacity.

In our case, the early diagnosis enable patient to actively and autonomously engage in decision-making, before this capacity starts to be affected by illness. This way, the information necessary to understand the symptoms is found out early, which allows taking decisions regarding the future, how medical and psychosocial nursing will be carried out and an improved quality of life.

TRUNK AND HIP ANALYSIS DURING GAIT IN POST-DISCECTOMY ACTIVE LUMBAR STABILIZATION (Abstract): This paper presents a post-discectomy rehabilitation program through active lumbar stabilization with focus on trunk and hip movement analysis during gait. Material and methods: Analysis consisted of a kinematic gait study, with kinematic point tracking and software data processing in MATLAB. The analysis was performed on a patient with L5-S1 discectomy. The purpose was to track progress and change in trunk and hip during the rehabilitation program and to establish a relationship between trunk and hip movement during gait, in regards to the patient's rehabilitation program. Results: Trunk and hip analysis during gait showed significant differences in patient hip and trunk rotational movement between the three analyzed readings of the patients. Changes were found in both left and right hip flexion-extension coupling and flexion in terminal swing. The rotational movement of the trunk is reduced in a more physiological margin from -13.4 to -1.0 anterior-posterior movement which correlates with un improved in transversal rotation. The analysis made for hip and trunk synchronization revealed an increased synchronization after the end of the functional reeducation program. Conclusions: This method allowed to evaluate changes in trunk and hip motion during gait. Tracking and visualizing the motion between trunk and hip during gait gives a better understanding of the importance of each movement and the strong link between gait phase coordination and motion angle amplitude. It gives a new perspective on the rehabilitation process that targets lumbar stabilization. **Keywords**: REHABILITATION, GAIT ANALYSIS, DISK HERNIATION.

Lumbar discectomy is one of the most common surgical treatment in lumbar disc herniation. The main goal of the postoperative rehabilitation program is to restore lower spine movement and strength of the corresponding muscles.

To our knowledge, trunk and hip kinematic data during gait has not been yet clearly defined. There is a general understanding on flexion, extension, rotational movements and synchronous phenomena that occur between trunk and hip during gait. There are few studies (1, 2,3) that describe a kinematic analysis of the relationship between trunk movement and hip/pelvis movement during gait. In a kin-

ematic study (3), overlapping trunk and hip curves results in a common area. This common area describes the time frame where trunk and hip, align. Shape, size and other detail aspects of the area are important to determine imbalanced movements and muscle realignment need. Also, the trunk and hip coordination in gait phases is important as de-synchronization affects gait performance as well as pathological kinematic angles (4). It is important to note that this type of analysis does not have a scientific study reference yet, but has the foundation of what is already known in terms of trunk and hip kinematics.

During the rehabilitation program, the physiotherapy specialist follows an already established protocol, making some changes to accommodate the patient's current state and health history.

Lack of objective feedback in a rehabilitation physiotherapy type program is an issue. Pain scales such as Visual Analog Scale (VAS), movement tests such as Prone Instability Test, Passive Lumbar Extension Test and Lumbar Dynamometry are current evaluation test that quantify the progress of a rehabilitation program.

MATERIALS AND METHOD

The study was conducted in the Physiokinesiotherapy and Rehabilitation Center of "Grigore T. Popa" University of Medicine and Pharmacy Iasi.

The patient studied was a 37 years old male, of height 1.8 m and of weight 70 kg. He came to the center for rehabilitation after having a lumbar discectomy surgery at L5-S1 level 4 weeks prior. The rehabilitation protocol for our patient consisted of a four-stage program of active lumbar stabilization(ALS) exercises (5). The four stages are muscle re-education, static stabilization, dynamic stabilization and functional activities. In total, for our patient, the rehabilitation program consisted of 30 sessions set throughout a period of 4 weeks.

Gait analysis was performed 3 times. First evaluation was made at the start of the rehabilitation program to assess the initial patient's gait and will be referred to as A1 in the study. The second time was after 15 sessions, referred to as A2, and the third time at the end of the rehabilitation program referred to as A3.

To perform the gait analysis, the patient was asked to walk at a normal walking speed rate covering a distance of 10 m, back and forth for 10 times. Body landmarks were established for trunk, pelvis, hip, and knee. Four digital cameras were positioned to record from the front, back, left and right. Video analysis was performed using DLTdv3 digitizing toolbox for MATLAB® (6) to track the landmarks. General functions in MATLAB® where used to obtain gait angles for each gait segment, plotting values and data comparison. We used MATLAB® version R2007b with license number 336.240.

Values were obtained for speed, step length, duration of gait phases and motion angles at each gait segment. The angles were plotted to obtain kinematic gait graphs.

Regarding these kinematic gait graphs, the overlapping area mentioned earlier occurs during gait between the Terminal Stance and Initial Swing phases (3). During gait, this is the interval where the pelvis/hip and the trunk align. In normal gait and at normal walking speed the trunk rotates counter clockwise with forward leg movement, all while the pelvis and hip rotate in the opposite direction. The coor-

dination of trunk and hip movement is important for an optimal and efficient gait.

By analyzing these areas, our focus was to find a relationship between trunk and hip kinematics with respect to gait phases and follow progress throughout the rehabilitation process. This was also a method of quantifying the link between trunk and hip movement during gait.

RESULTS AND DISCUSSION

For a better understanding of our patient's trunk and hip movement coordination during gait we first made a general analysis of hip kinematics in sagittal plane. In figure 1 are plotted the left hip angles during gait for each of the three-gait analysis made. Of interest to the study was the Pre-swing phase timing during gait and differences in angle amplitudes.

The red line corresponds to A1, before rehabilitation started, the light blue line corresponds to A2 and the dark blue line corresponds to A3. There is a considerable difference in the graphs showing a clear change of patient's gait at hip level (fig. 1).

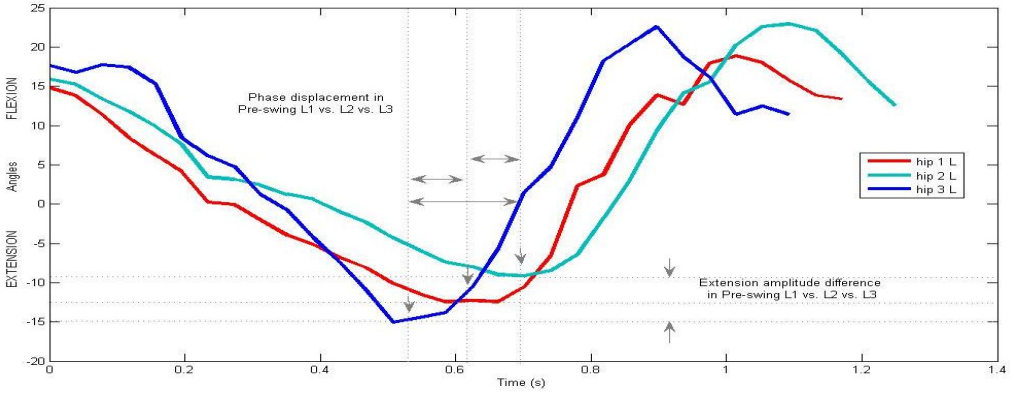

Fig. 1. Comparison between first, second and third gait analysis of hip movement angles in sagittal plane (left side)

At initial contact in A1the hip flexion was 15°, half the value of the average normal (7). During terminal stance, the hip reaches a maximum of 13° of extension and then continues with a flexion of approximately 19° during mid-swing, ending the cycle with a decrease in flexion to 18° in terminal swing. The values found are significantly lower than the normal averages (7) and describe a deficit in movement amplitudes during gait, both in flexion and extension of the hip. In A2 flexion at initial contact increases to 16°, extension decreases at 9° in pre-swing and flexion increases at 23° in terminal swing. At this stage, values get closer to normal range except for extension in pre-swing. In A3, flexion at initial contact increases to 18°, extension increases at 15° in pre-swing and flexion remains at 23° in terminal swing. A3 exhibits values that are in normal range (7). This shows a clear progress and a good rehabilitation of our patient.

In figure 2 the dotted lines correspond to the right hip for each of the analyses and have corresponding colors to the ones from the left side. The graphs for the right side are reversed so that they match the left side

for a better comparison. This comparison was made to illustrate if there were any differences in values or coordination of gait phases between left and right hip.

In A1 there is a difference in pre-swing phase timing between left and right (marked with red arrows). This de-synchronization is also present in A2 but the difference between the phase timing is smaller than in A1(phase timing is marked with light blue arrows).

In A3 there is a clear synchronization between left and right (marked with dark blue arrows). This shows that left and right hip match in phase timing and have very similar motion amplitudes. To get more into detail, in pre-swing, when the pelvis drops it is stabilized by a complex set of muscles (rectus abdominals, external oblique, iliopsoas, low back extensors, hip extensors and hip flexors). If these muscles from one side do not work in synch with the ones from the opposite side than it translates on the graph in a difference in amplitude and timing of gait phase.

In figure 3 are plotted the left trunk angles in sagittal plane during gait for each of the three-gait analysis made. For an easy reference, we kept the colors corresponding the each of the gait analysis.

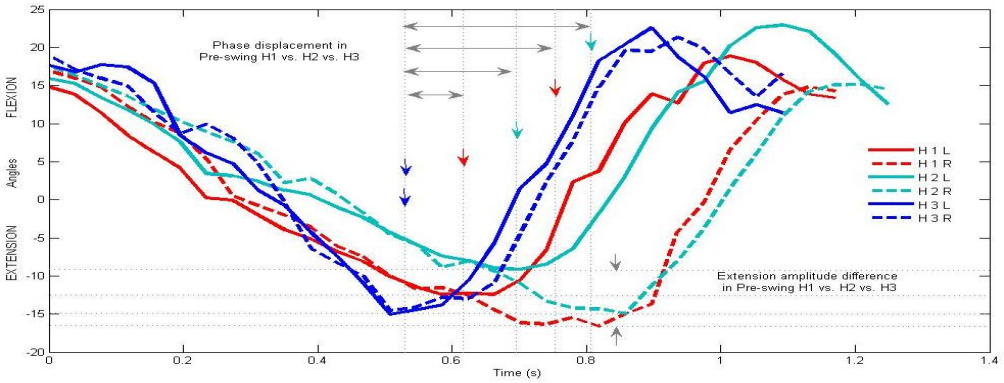

Fig. 2. Comparison between first, second and third gait analysis of hip movement angles in sagittal plane (left and right side)

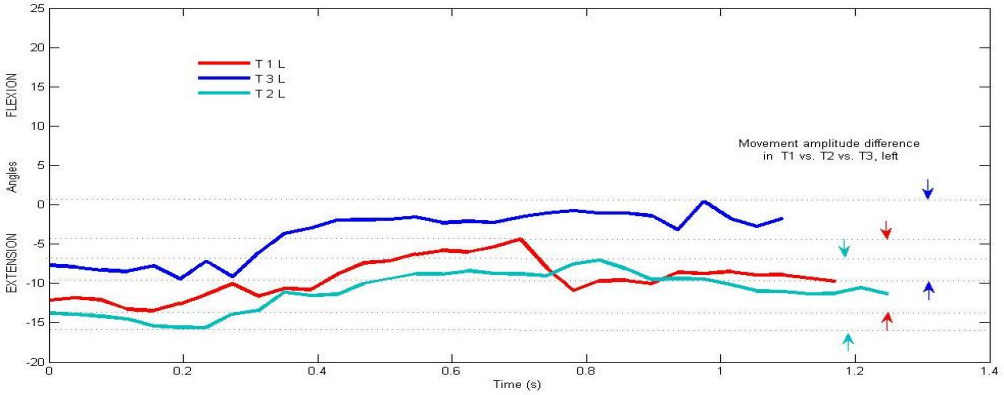

Fig. 3. Comparison between first, second and third gait analysis of trunk movement angles in sagittal plane (left side)

In A1, trunk remains in a constant hyper-extension with values varying with gait phases. The trunk oscillates in sagittal plane with values raging in the interval of (-13, -4). At initial contact trunk is extended at -13°, which is more than double the average normal value (8).

In A2 there is still a predominance of hyper-extension of the trunk but not as fluctuating in amplitude as before rehabilitation started.

However, in A3 trunk extension is significantly reduced. The arrows in the right in corresponding colors show the amplitude interval for trunk in each gait analysis. In A3 the trunk oscillates in sagittal plane with approximate values raging in the interval of (-10, 0). Compared to A1, at initial contact in A3, trunk is extended at approximately 7°.

In fig. 4 the dotted lines correspond to the right trunk for each of the analyses and have corresponding colors to the ones from the left side. The graphs for the right side are reversed so that they match the left side for a better comparison. A1 and A2 do not have symmetrical left versus right trunk graphs. There is also a difference in flexion moment in A1 where peak areas do not overlap. A3 shows a similarity between left and right curve with a slight bigger value of flexion on the right side.

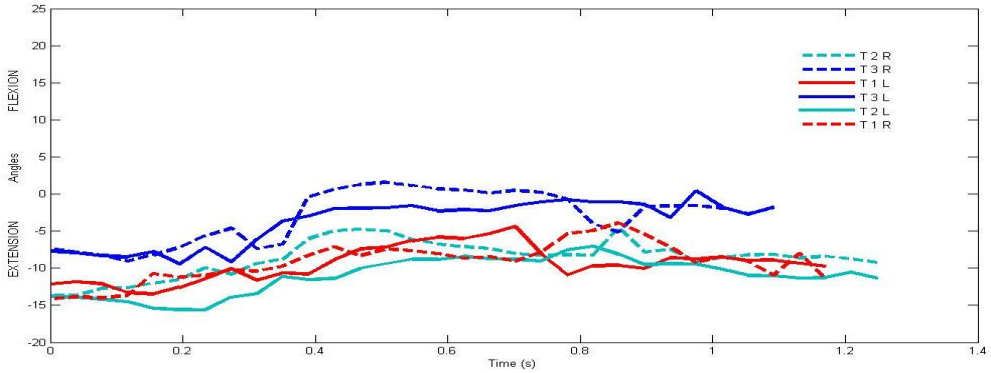

Fig. 4. Comparison between first, second and third gait analysis of trunk movement angles in sagittal plane (left and right side)

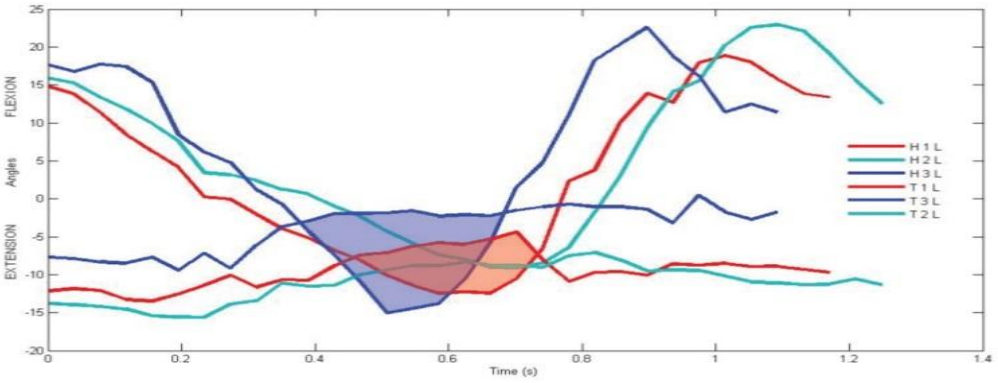

Fig. 5. Overlapping area comparison between trunk and hip movement angles in first, second and third gait analysis (left side)

In figure 5 are highlighted the overlapping areas between hip and trunk gait graphs. Each overlapping area has the color corresponding to the graphs from A1, A2 and A3 gait analysis. As explained earlier this marks the time frame where hip/pelvis and trunk align.

Overlapping area in A3 is greatest and is located at the middle of the gait cycle. This translates in a good motion synchronization. Peak of trunk curve is when trunk bends forward to move the center of mass outside the base of support. Lowest point on the hip gait graph is when hip is in maximum extension and prepares for toe off to continue in swing phase. Therefore, an increase in sagittal plane flexion of trunk would raise the curve making the overlapping area bigger. Also, a decrease of hip extension would raise the curve, making the area smaller. Ideally, there must be a balance between motions of segments.

Regarding the position of the overlapping area with respect to the gait curves, the optimum position should be in the middle of both curves. That is because maximum hip extension and trunk flexion should occur at approximately 50% of gait cycle. In A3 overlapping area occurs as normal.

In figure 6 are included the graphs corresponding to hip and trunk from right side and are highlighted the overlapping areas between hip and trunk gait graphs. For a better and clear view, only graphs from A1 and A3 are shown.

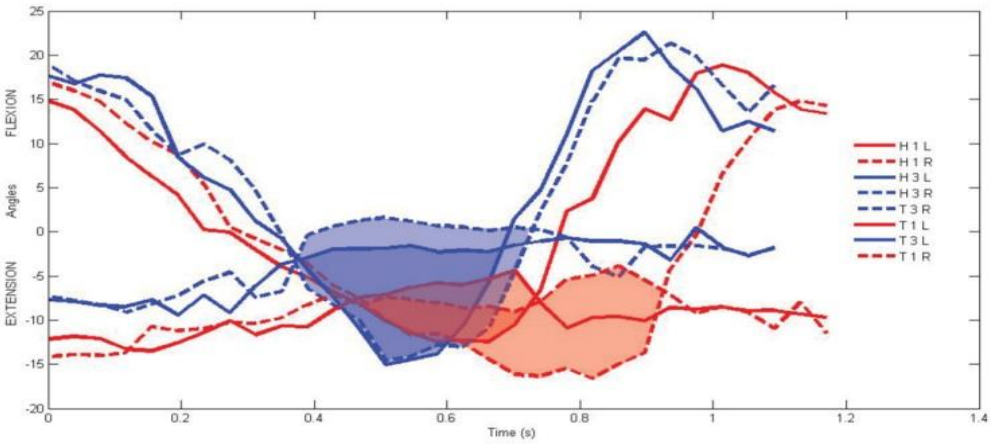

Fig. 6. Overlapping area comparison between trunk and hip movement angles in first and third gait analysis (left and right side)

After the analysis of the kinematics of trunk-hip related rotational movement we can conclude that the transvers rotational movement of the hip and trunk improved. That means that the patient could move with a hire discrepancy between the two segments because of the increased dynamic stability which promoted higher transversal rotational movement.

We found similar results in the only two articles (9, 10) from the scientific literature that covers this subject. The difference is that this studies compared normal versus pathological lower back pain (LBP) patients. They found that the LBP patients compared to healthy people had a more

rigid and less flexible pelvis-thorax coordination.

A significant difference can be seen between the left and right side in A1 overlapping areas. This translates in an overall pronounced and de-synchronized rotation of hip and trunk. Visually, the right-side area is bigger than the left side. In A3, areas are similar in shape and size. This shows a good motion synchronization and amplitude control by muscles that can lead to a decrease in stress forces on lumbar disks.

CONCLUSIONS

Performance and efficiency feedback in rehabilitation program was defined and tracked through a kinematic analysis system. We defined the relationship of trunk and hip motion during gait with respect to the gait phases that allowed for a better understanding of lower back, hip and pelvis muscle action and synchronization during the rehabilitation program. The method allowed for tracking change in trunk and hip motion during gait.

Our method of tracking and visualizing the motion between trunk and hip during gait gives a better understanding of the importance of each movement and the strong link between gait phase coordination and motion angle amplitude. Therefor this also puts a new perspective on the rehabilitation process that targets lumbar, pelvis and hip muscles showing the importance of muscle alignment and synchronization for optimum motion stabilization.

DOES THE THEORY OF RELATIVITY APPLY TO CARDIOVASCULAR RISK? CHANGES IN THE SPECTRUM OF CARDIOVASCULAR RISK FACTORS IN ELDERLY PATIENTS – CASE REPORT

DOES THE THEORY OF RELATIVITY APPLY TO CARDIOVASCULAR RISK? CHANGES IN THE SPECTRUM OF CARDIOVASCULAR RISK FACTORS IN ELDERLY PATIENT– CASE REPORT (Abstract): The cardiovascular system balance can be disturbed by a various number of factors, some of them modifiable and others, such as age, which cannot be influenced. In the context of aging associated with such comorbidities as diabetes mellitus and rheumatoid arthritis, we wonder if the classical cardiovascular risk factors are enough to assess the probability of cardiac decompensation, or other factors may be involved. We present the case of a 76-year-old patient known with permanent atrial fibrillation, high blood pressure, diabetes mellitus, hypodiastolic heart failure and rheumatoid arthritis who was admitted with cardiac decompensation without evident cause and despite apparent therapeutic compliance. Geriatric assessment revealed marked mnesic and cognition deficit, malnutrition risk, dependency, depression and frailty. In such patients, the role of cardiac sarcopenia and rheumatoid arthritis in the decline of the cardiac function and patient outcome must be assessed and then managed. **Keywords**: ELDERLY, CARDIOVASCULAR RISK FACTORS, SARCOPENIA, RHEUMATOID ARTHRITIS.

In the context of the increased lifespan, the diseases afflicting the elderly occupy an even more important place in the current medical practice. We are now witnessing major changes in the spectrum of cardiovascular risk factors in elderly patients. Beside age itself, several other risk factors must be considered. Frailty and its core element – sarcopenia and even cardiac sarcopenia – is one of these factors. Also, the presence of several comorbidities, known risk factors (diabetes mellitus, arterial hypertension) or "silent risk factors" (connective tissue diseases, rheumatoid arthritis), influence the outcomes of elderly patients with cardiovascular disorders.

CASE REPORT

We present the case of a 76-year-old patient with an about one-year history of permanent atrial fibrillation, grade 3 arterial hypertension (AHT), diabetes mellitus type 2, hypodiastolic heart failure and rheumatoid arthritis (RA) admitted to the Clinic of Geriatrics-Gerontology, "Dr. C.I. Parhon" Hospital Iasi. During the last

months, the patient noticed an accelerated and progressive deterioration of cardiac function, despite the apparent therapeutic compliance and without evident cause.

The patient was at home, on treatment with digitalis, diuretic, platelet antiaggregant and long-acting nitrate drugs. The treatment of rheumatoid arthritis was previously discontinued because of the appearance of side effects (iatrogenic thrombocytopenia). Also, the patient was partially bedridden.

The geriatric assessment revealed: marked mnesic and cognition deficit (MMSE=23/30), risk of malnutrition (MNA 18/30), a high level of dependency (ADL=4/6, IADL=1/8), moderate depression (GDS=7) and frailty (FRIED score=4/5).

Biologically, an inflammatory syndrome (VSH 50 mm/h), mild anemia (Hb=10.1 mg/dl), fibrin degradation products ++ and lower tract urinary infection were found.

Electrocardiogram (ECG) showed atrial fibrillation and alterations in the terminal phase in the inferolateral territory.

Chest radiograph revealed calcified aortic knob, *g*lobally increased heart size (cardiothoracic index 0.75), swelling of the left middle arch, opacification of both lung bases, pulmonary condensation syndrome more marked in the right lung, enlarged right pulmonary hilum, left fissure (fig.1), appearance obviously contrasting to the radiologic image recorded one year earlier (fig. 2).

Echocardiography showed cardiac cavities globally dilated. Also found was a systolic dysfunction with reduction of left ventricular ejection fraction (LVEF) from 56% one year earlier to 47% on current admission. An important finding was severe pulmonary arterial hypertension (PAH), previously absent.

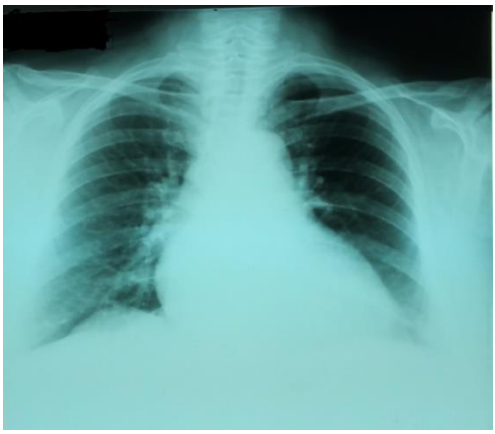

Fig. 1. Chest radiograph, obtained one year before current admission

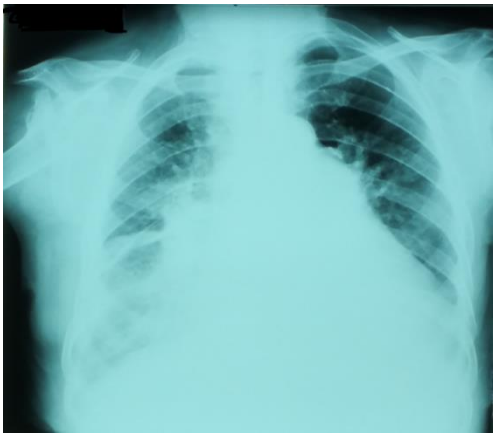

Fig. 2. Chest radiograph on current admission

The patient presented diabetes mellitus and AHT as major predictable risk factors for cardiovascular disease. However, the sudden onset of heart failure and occurrence of severe PAH in less than six months after the initial presentation despite therapeutic compliance cannot be explained by the above mentioned risk factors. This fact made us re-evaluate the cardiovascular

risk of the patient and consider the patient-specific risk factors. Thus, the impact of pulmonary embolism, cardiac sarcopenia and comorbidities, an important role being occupied by rheumatoid arthritis was explored. Geriatric assessment confirmed clinical frailty and suggested the possible presence of clinically manifest cardiac sarcopenia, especially since the patient was bedridden because of heart failure symptoms. A MRI was recommended, but the patient postponed it.

The analysis of comorbidities, corroborated with the data in the literature and clinical presentation of the patient raised the problem of the role of rheumatoid disease in the occurrence and progression of cardiac affection.

In the given situation, we felt necessary to reduce the risk of thromboembolism induced by arrhythmia and prolonged immobilization. Thus an anticoagulant therapy with calcium nadroparin was initiated. Then we focused our attention on maintaining the cardiac function by digitals therapy and the correction of edemas with diuretic therapy with intravenous furosemide followed by the oral administration of a combination of a loop diuretic and a potassium sparing diuretic (spironolactone). The symptoms of cardiac decompensation were improved, edemas reduced and the patient lost 12.5 kg after 13 days of treatment.

DISCUSSION

According to the Framingham study (1), old age together with smoking, diabetes mellitus (DM), AHT, high levels of LDL-C and respectively low levels of HDL-C are major cardiovascular risk factors. Nevertheless, the particularities of the elderly patient together with the presence of multiple associated comorbidities can significantly modify the cardiovascular risk. This fact can lead to atypical symptoms and course of cardiac diseases, as well as to an unforeseeable rapid progression. Among the elderly, heart failure affects 1% of the subjects and is responsible for about 1/5 of the annual hospitalizations in patients over 65 years old (2).

The structural and functional aging changes in the heart and blood vessels determine *per se* a significant increase in cardiovascular risk in the elderly patient (3). Thus, there is a decrease in the number of cardiac myocytes directly proportional to age. This fact determines the consecutive occurrence of compensatory hypertrophy of the remaining cells and the proliferation of the tissue matrix following the alteration of the fibroblastic function. Some molecular changes occur, with perturbation of ionic balance and abnormalities of myocardial relaxation in protodiastole (4). These structural and functional ventricular changes lead to left ventricular dilatation and reduced LVEF, markers of cardiac sarcopenia in elderly patients (5). Their onset is at the beginning of adult life and continues until old age when they stop, and a significant reduction in myocardial mass occurs, indicating the presence of cardiac sarcopenia (6). According to the recommendations of the European Working Group on Sarcopenia in Older People, sarcopenia is defined as a quantitative and functional reduction in muscle tissue (7). A frequent association between skeletal muscle loss in the elderly and heart failure was found. However, the identification of this entity at heart level raises serious diagnostic problems, because of the high difficulty of evaluation.

A special attention should be given to the presence of the RA, as its prevalence increases with the increasing lifespan of the

population. This disease affects 1% of the world population and 5% of the population over 65 years (8), being often associated with cardiovascular complications. In Romania, it is estimated that RA affects up to 3% of elderly population (9).

A series of studies have analyzed the relation between RA and cardiovascular disorder. Among these patients it was noticed an increased cardiovascular mortality, which can be attributed on one side to accelerated atherosclerosis and, on the other side, to the development of heart failure. Also, the incidence of myocardial infarction in these patients is high, and mortality within the first 30 days after an ischemic coronary event is higher. From this point of view, we can consider that the cardiovascular risk of the RA patients is comparable to that of the diabetic patients (10).

The cardiovascular disease can begin before the first symptoms of RA, with the onset of subclinical immunological changes. The pathophysiological substrate is represented, most probably, by the pro-inflammatory status. At molecular level incriminated are IL-6 and TNF-α by their relationship with insulin-resistance, as promoters of accelerated atherosclerosis (ATS) (11). At the same time, a correlation between the markers of the inflammation and the progression of ATS was noticed. High levels of C reactive protein (CRP) are considered an independent predictor of cardiovascular mortality in patients newly diagnosed with RA (10). At the same time, the erythrocyte sedimentation rate (ESR) level indicates the effect of inflammation on intima-media thickness of the vessels. It was noticed that most patients with RA present ESR levels over 40 mm/h in the first 6 months after the occurrence of heart failure (12).

The main cardiac changes in patients with RA are represented by asymptomatic diastolic dysfunction, left ventricular hypertrophy (LVH), increment in right ventricular pressure and development of PAH. An echocardiographic study (13) identified in these patients the presence of diastolic dysfunction (32.4% of the cases), systolic dysfunction (18.1% of the cases), but also of PAH in about half of the cases.

Patients with RA have twice the risk of developing heart failure, which thus becomes the main cause of mortality. In most cases, its occurrence cannot be explained by the presence of traditional cardiovascular risk factors. It was noticed that, even if LVEF was preserved in most cases, mortality at 1 year following heart failure was higher in patients with RA compared with non-RA patients (2).

There are several studies that identified a high level of association between RA and PH. The presence of the latter represents a negative prognostic factor, indicating an average survival of 2-3 years from the time of symptom occurrence (8, 14).

As to the therapeutic strategy which should be considered in the case of the association of RA with cardiovascular disease, until now the information is contradictory. Angiotensin converting enzyme inhibitors are known for their beneficial effects in the treatment of PAH (15). Certain studies (10) recommended the use of angiotensin converting enzyme inhibitors, since they improve the endothelial dysfunction. Also statins could prove useful, due to their effect against arterial stiffness. By using anti-TNF-α agents, it is possible to have benefits in improving the cardiac function in the patients with incipient heart failure (11), but further studies are necessary in this regard.

CONCLUSIONS

In our study, the development and accelerated progression of cardiac disease cannot be explained only by the presence of traditional cardiovascular risk factors, but also by a series of other factors.

Thus, frailty, malnutrition, dependency, depression, which are characteristic to the elderly patients, represent a vicious circle that acts as a factor promoting the rapidly progressive decline of cardiac function. Sarcopenia, both in the skeletal muscles and especially in the cardiac muscle, appears as a deceiving pathological entity, which creates serious diagnostic and therapeutic problems. It is imperative to consider all the existing comorbidities. Nowadays, pathological entities, once characteristic to a relatively younger patient, are associated with all ages, as is the case of RA. The association of other factors, such as cardiac sarcopenia and frailty, may modify the course of heart failure and strongly interfere with the prognosis of these patients. Intensive treatment of all particular conditions of senior patients will improve their quality of life and will reduce disabilities and dependency.

NEUROPSYCHOLOGICAL GROUNDS IN THE AWAKE BRAIN SURGERY (Abstract): Traditionally, the awake cerebral neurosurgical interventions are carried out when the primary motor areas and the areas involved in language are concerned. This procedure is also known as *mapping* (Intraoperative Brain Mapping). The intraoperative neuropsychological protocol supposes the setting of a list of steps and tasks that the patient must perform during the surgery, taking into account the lesion localization (both the cortical and the subcortical structures), the cognitive functions involved and the individual particularities of each patient. As a result of the high validity of certain tests, we propose a common minimal set of tests, which can allow a minimal standardization and replicability. **Keywords**: BRAIN AWAKE SURGERY, BRAIN MAPPING, INTRAOPERATIVE NEUROPSYCHOLOGICAL PROTOCOL.

Relatively recent archaeological findings show that cranium trepanation is not a new procedure, as we could believe. She has been successfully carried out long ago the appearance of the general anesthesia. A number of skulls discovered in Peru shows a healing percentage of 55% of 214 patients (1). From several points of view, the modern era of awake craniotomy starts more than 50 years ago, when Wilder Penfield and Andre Pasquet (1) published their reference work regarding the surgical and anesthetic aspects of the surgical interventions after the local and intermittent administration of sedatives and analgesic drugs. However, as chronological attestation, Penfield seems to be preceded in the cortical stimulation by Robert Bartholow (1) early from 1874. This one describes the case of a 30-year-old patient, Mary Rafferty, who addresses to him for a consultation, with a cranial orifice of 51 mm, most probably acquired after a scalp carcinoma. Inspired by the testing on animals of David Farrier, Bartholow (1) applies a low-intensity electric current in different areas of the exposed brain of his patient. These stimulations lead to the appearance of certain motor reactions. Several concepts highlighted by Penfield and Pasquet are still relevant.

The cognitive neurosciences benefit nowadays from a better knowledge of the neuronal grounds of the cognitive processes

and their clinical applications, mostly in the neurosurgical practice. Over the last decades, remarkable progress has been made in the non-invasive cortical mapping (magnetoencephalography, functional MRI), but also at the level of the invasive mapping (awake intraoperative cortical stimulation) (2). The main reason in using awake craniotomy is the cortical *mapping*, the observation of cortical stimulation effects on the cerebral functions and at the same time the reduction of lesions in the adjacent eloquent tissue during tumor resection. Traditionally, the awake cerebral neurosurgical interventions are carried out when the primary motor areas and the areas involved in language are concerned, but are not limited to them.

After the analysis of a numbers of articles, we were not very surprised to find out that the non-verbal functions mapping received less attention, even though the functional deficits, other than aphasia, can have an equally strong impact on patient's activities and on his quality of life. Visual-spatial and cognitive deficits are more frequently reported after the detailed and extended neuropsychological assessments. In several countries, a diagnostic of hemianopsia or unilateral spatial neglect leads to the interdiction to drive (3).

Verbal and nonverbal functions' mapping in the dominant and nondominant hemisphere - electrical brain mapping findings

Language mapping

The perisylvian areas of the dominant left hemisphere are classically described as being involved in language (4). Consequently, specific language tasks have been enforced during surgeries for the tumors located in these areas, in order to avoid permanent postoperative deficits of the written or oral language. For instance, the spontaneous speaking, counting, objects and actions naming, recognizing famous personalities, reading and written have been used for the mapping of the superior and posterior areas of the temporal lobe, inferior parietal lobe and lateral part of the frontal lobe.

Because of the intraoperative tasks, the electric mapping made possible the establishment of anatomic and functional correlations which led to an updated vision of language connections in general. Therefore, a new paradigm was proposed, based on a parallel and interactive distribution model of the network at a higher scale. This model includes an anterior path which connects the orbitofrontal, prefrontal and dorsolateral prefrontal areas with the temporo-occipito-parietal regions, by means of the inferior fronto-occipital fasciculus. This anterior path is involved in the semantic processing and the direct electrical stimulation during the denomination tests determines semantic par aphasias. Moreover, the posterior path interesting the superior longitudinal fasciculus, which connects the inferior frontal gyrus and the ventral premotor cortex with the superior temporal cortex and passes through the inferior parietal lobe, is involved in the articulatory components of language. The direct electrical stimulation of these structures causes phonemic par aphasias and dysarthria. Recent articles presenting the morbidity profile describe a percentage of 13% of the patients with dysphasia after an aggressive resection of parietal lobe gliomas (5).

Other cortico-subcortical regions of the left hemisphere are also involved in speech articulation and namely, the left additional motor area (dominant hemisphere), the anterior part of the insula and the lentiform

nucleus causing dysarthria upon electrical stimulation. These circuits converge towards a final common path in sensorial-motor primary cortex causing a dysarthria or anarthria when stimulated during speech (6). Moreover, this extended network is modulated by cortico-striate circuits, provoking language control troubles or self-regulation upon electrical stimulation. More than that, the posterior part of the inferior longitudinal fasciculus plays a crucial role in the visual recognition in the image denomination tasks, but also in lexical items tasks. A subordinate network serving to the written language was also described, comprising the additional motor area, the Exner area and the superior and inferior parietal lobe, but also the superior longitudinal fasciculus.

Language mapping in patients speaking several languages or the mapping of sentence translation has been carried out in bilingual and polyglot patients. Therefore, a sub circuit involved in language, dedicated to the change/switching has also been remarked. The control of choosing the spoken language can temporarily be affected mainly during the stimulation of the left caudate nucleus (7) (which provokes perseverations), showing at the same time its role in the executive functions, such as selection, inhibition, planning and attention processing.

Finally, the right hemisphere, described as having a "mirror" configuration is involved in prosody, the semantic processing of words and of the speech, the processing of the context and of language pragmatic abilities, beside its involvement in executive functions, mainly the attention and the working memory.

Nonlanguage mapping

With regard to the sensorial-motor functions, the classical intraoperative neurophysiological monitoring using evoked potentials or motor stimulation during the general anesthesia, allows the mapping through muscle contractions during the procedure and prevents therefore hemiplegia. But movement is not action. By opposition, the direct electrical stimulation in patients in vigil/awake phase allows the objectivisation of certain high level perseverations in the visual-spatial processing due to the mapping, not only of the motor function, but also of the somato-sensorial and visual function and even of the spatial cognition. The execution of movements in the contralateral hemi body, when the resection comes very close to the pyramidal and thalamocortical paths, brings valuable information in preserving the fine motor activity, essential for a normal life standard.

In the same train of thought, a complete hemianopsia can have a major negative impact on patient's life quality, affecting his daily activities, mainly because the development of this type of deficiency leads in most cases to the interdiction to drive. Visual pathways mapping is possible by using the direct electrical stimulation of the awake patient in case of tumors from temporal-occipital junction, through the appearance upon stimulation of the positive visual responses (phosphines or illusions such as metamorphopsia) and negative, such as visual field defects or blurred vision (8). Therefore, hemianopsia or the visual field deficits should be avoided.

Moreover, the cortical areas (mainly the right supramarginal gyrus or the superior temporal cortex) as subcortical paths (the right superior longitudinal fasciculus) serving to the spatial cognition, can be identified and preserved during the resection of

the parieto-occipital junction, asking the patient to carry out tests such as the line bisection task (the patient must draw a sign at the middle of a line and one presents to the patient a range of several lines placed in different positions as compared to the margins of the paper or of the computer screen). The cerebral structures highlighting the vestibular functions, mainly the superior temporal gyrus and the parietal-insular cortex, connected by the superior longitudinal fasciculus of the "non-dominant" hemisphere for language, can also be objectivized and spared during the intervention for the temporal-parietal lesions, using the direct electrical stimulation in the awake condition, having as result the reproducible vertigo.

Other superior cognitive functions received less attention, but they can however be tested during the awake mapping procedure (for instance, calculation tests during the left parietal resections, mainly in the left angular gyrus). The stimulations during the memorization, retention/ storage or delayed memory were also used for the mapping of the mnesic function, by means of the awake craniotomy procedure, involving the premotor areas in the dominant hemisphere, the left anterior temporal lobe or the fornix. The frontal visual field, which provokes saccades and is related to the attention and to the working memory, was also investigated. The use of a non-verbal semantic association test during the intraoperative stimulation highlighted the neural basis, accentuating the multimodal semantic processing (verbal and non-verbal).

The trans-modal (visual-verbal) association tasks were carried out by the patients during the resections of tumors located between the left dorsolateral prefrontal cortex and the temporal posterior cortex, which is connected through the inferior occipito-frontal inferior fasciculus. Emotional aspects of feeling recognition at the level of the superior part of the face, at the level of the eyes ("mirror of the soul") were also described in patients with posterior perisylvian tumors. Finally, the use of a song interpretation task in patients that were vocal singers was reported in five cases, describing dissociations between speech and melodicism outside the primary sensorial-motor area.

The need to develop a personalized protocol

We must be aware of the fact that the eloquence of the functional areas cannot be accurately anticipated only based on anatomic structures. The anatomic knowledge is necessary but not sufficient to operate with a high degree of certainty mostly in the "functional neurooncology". Therefore, neurosurgeons must benefit from the advantages of the direct electrical stimulation technique in order to develop customized protocols for each patient, rather according to the functional borders than to the tumor borders in gliomas resection. In order to support these ideas, a major anatomical and functional individual variability was proved, by using the functional neuroimagery in healthy volunteers, but also by using the direct electrical stimulation in patients with epilepsy. In a recent report, Ius et al. 2011 (9), proposed an atlas of the functional resections in patients who developed a low-grade glioma, mainly represented by the main association paths which should not be resected if one wants to avoid permanent deficits. Moreover, the authors found eloquent areas which can be compensated, mainly at cortical level. The

authors concluded that the identification of a given functional area cannot be accurately carried out before the intervention because of the plasticity, conferring a crucial role to the electric mapping for the "online" anatomical and functional correlations and the preservation of the eloquent areas during the awake brain surgery.

Furthermore, the intraoperative mapping through direct electrical stimulation is not only an instrument, but it is also considered an access door to the functional network which allows us a better understanding of the neural basis, by means of the cerebral processes. The neurophysiologists brought into discussion ethical aspects of this invasive technique, in which we must not forget that the main objective is patient's benefit through the maximal resection and the preservation of the important functions. As a consequence, it is important to find equilibrium in the number of tests strictly necessary in order to preserve patient's life quality and not enforce too many tests which can be time consuming over the intervention, inefficient and possibly harmful.

A multidisciplinary approach involving neurosurgeons, neurologists, neuropsychologists and speech therapists is crucial in order to build an adequate intraoperative protocol and practically adapted to each individual patient, with the selection, to the possible extent, of sensitive tests capable of assessing more than one cerebral function. For instance, the classical picture naming task allows an integrated, complex testing which involves visual recognition, semantic processing, lexical access/vocabulary, phonological decoding and verbal production at the same time. An accurate analysis, in real time of the possible functional deficiencies produced by direct electrical stimulation or the resection itself should be carried out by a specialist during the tumor resection.

The selection of the intraoperative tasks must be based both on the features of the patient and of the lesion. The neuropsychologist must first of all determine the hemisphere dominance. The identification of the manual dominance is not sufficient, as cases of postoperative crossed aphasia were reported. Therefore, the most important factor in assessing the cerebral dominance is the existence of certain preoperative language transformations, even subtle ones, highlighted by a detailed neuropsychological examination.

Furthermore, patient life features (job, hobby, habits) must play an important role in selecting the intraoperative tasks. As compared to a standard protocol, one must use specific tests in order to assess the individual needs of each patient. For instance, a calculation test can be necessary for a mathematics teacher, mostly when the lesion is located in the left parietal lobe; a reasoning task is important for a lawyer; a spatial cognition task is crucial for a military strategist or for a cartographer, while a synthesis and analysis and mental rotation task is absolutely necessary for a draftsman or an architect.

Lesion features (localization, volume) must also be taken into account. A lesion does not affect one specific anatomic structure only, but it can involve the entire cerebral functional network.

Preoperative psychological counseling and assessment

It is recommended to explain to the patient the intraoperative procedure and to present him to the members of the surgical team, but also to perform a neuropsycho-

logical assessment at least one day before the surgical intervention. The neuropsychological assessment aims at determining the base line of neurocognitive functions, carrying out the tests included in the intraoperative protocol, for familiarization purposes and for removing the items causing difficulties to the patient, so as not to obtain false negative intraoperative responses. The involuntary movements, but also the inhibition of the voluntary ones can create to the patient a discomfort, anxiety accompanied by vegetative manifestations and even the alteration of the vital signs (10, 11). All these manifestations without an acceptance and a good compliance of the patient, based on the information and gaining the trust of the patient can threaten the proper development of the neurosurgical procedure. Therefore, besides the neuropsychological assessment sessions, the patient is informed with regard to the neurosurgical technique and procedure to which he will be subject and one shall explain to him the importance of his cooperation – he shall be made aware of the need to have an active – participative behavior during the surgery. Moreover, he shall be informed that during the stimulation can appear movements or reactions that the patient did not want to perform or, to the contrary, that he wants to perform, but he is not able to do so. He must be assured that these incidents are transient and are caused by the direct cortical stimulation and will not have long-term consequences. As we already mentioned, it is important that the intraoperative neuropsychological protocol be customized, adapted according to the interested cerebral area, to the eventual existing deficits, so as to obtain an optimal cooperation of the patient and to take into account the individual features of the patient.

The neuropsychological assessment

It is recommended to perform an objective and reproducible neurocognitive assessment, in the preoperative and postoperative stages, not only for assessing the neurosurgical side effects on the cognitive functions, but also for adapting the eventual functional rehabilitation in accordance with the results of the neurocognitive assessment (12).

The neuropsychological protocol in the cortical *mapping* imposes the determination of the base line, by the assessment of the following functions: temporal and spatial orientation, orientation to self and others; verbal and visual memory, working and delayed memory; attention; language: fluency, comprehension and repetition, vocabulary, written form, calculation; visuospatial analysis and synthesis, mental rotation; testing the rough motor function and the fine movements; tactile, visual, auditory and proprioceptive sensitivity; executive functions, affective mood. Two neuropsychological assessment sessions are needed: preoperative and postoperative.

The intraoperative protocol

In light of the recent data, certain authors propose the drafting of a common minimal protocol, which can test not only the language, but also other cognitive functions, which can be enforced in preoperative, intraoperative and postoperative stages in the awake craniotomies (7). The objective would be to facilitate the replicability between different neuro-oncology centers.

Therefore, in order to meet a minimum standard on pre- and postoperative language testing, the protocol should include: a subjective questionnaire which can inventories

patient's plaints, handedness assessment, verbal fluency assessment / verbal spontaneity, a picture naming task with the calculation of the reaction time, a semantic fluency test, a timed semantic association task and also a timed vocabulary task. Of course, it is possible that the testing battery be extended in accordance with the variables related to the individual habits of the patient. The list of specific tasks can comprise the symbolic side of language - metaphors, repetition, vocabulary and written form.

The proposed protocol for testing the pre- and postoperative non-verbal functions can include: a subjective questionnaire which may inventorize patient's complaints also, the assessment of the information processing speed, the working memory, the executive functions (flexibility, inhibition), ideomotor and reflexive praxis and visuospatial cognition. And here appears the freedom of adding other specific tasks which will assess different aspects of social cognition or feelings, for instance.

Even though this set of tests is a proposal only, must be noted the fact that they have already been validated by favorable functional results, reported in hundreds of cases of extended resection of gliomas, carried out according to the functional limits. Besides language, it has been proven that intraoperative mapping also allowed the preservation of the complex neurocognitive functions, such as the working memory, the spatial cognition, calculation, linguistic switching in bilingual patients, trans-modal reasoning and executive functions.

CONCLUSIONS

The selection of the tests which shall constitute the intraoperative neuropsychological protocol must take into account both lesion localization and the functional areas involved, but also the subcortical association paths and the individual habits of the patient (job, hobby and customs). By the detailed assessment of the general condition of the patient, of the global cognitive functions and of the verbal skills, the psychologist has an important contribution in selecting the patients for the cortical mapping procedure, but also in its intraoperative development. The intraoperative neuropsychological protocol should contain a minimal common set of tests which would also allow a certain degree of standardization and statistical analysis, but which can be adapted to each patient with additional tests specific to the individual habits of each patient.

NEWS

PUBO-FEMURAL DISTANCE: A MORE ACCESSIBLE TECHNIQUE FOR EARLY DIAGNOSE OF DEVELOPMENTAL HIP DYSPLASIA IN NEWBORNS

Ultrasound imaging is, and has been for some time now, the gold standard for early diagnose of developmental hip dysplasia. Although there are several techniques, they usually require an experienced pediatric orthopedic surgeon or radiologist to interpret the results. The pubo-femural distance represents the distance between the lateral aspect of the pubic bone over the acetabular incisure and the medial surface of the cartilaginous epiphysis of the femoral head, both from a neutral position and with approximately 90 degrees hip flexion, without rotation, adduction or abduction. The coronal view necessary for obtaining a correct measurement is far more easily obtained that the incidence that the other methods require, making it a more accessible technique for the less experienced practitioners, but with similar results. This method could make possible a screening program for detecting developmental hip dysplasia, without the extensive training (Teixeira SR, Dalto VF, Maranho DA et al. Comparison between Graf method and pubo-femoral distance in neutral and flexion positions to diagnose developmental dysplasiaof the hip. *Eur. J.Rad.* 84 (2015) 301–306).

THE ACUTE SCROTUM IN CHILDREN (Abstract): The acute scrotum syndrome is a medical-surgical emergency and the recognition of this condition by both healthcare professionals and the general population may result into the patients' coming in earlier for medical examination and into the preservation of the gonad in case of torsion. The purpose of this retrospective analytical research is to point out specific epidemiological aspects in pediatric patients suffering from acute scrotum, and to review the existing diagnosis and treatment options. The study included 208 patients, of whom 16 with vanishing testis and 192 with acute scrotum (torsion of testis 25.5%, torsion of the hydatid of Morgagni 68.2%, epididymo-orchitis 5.2%). The torsion of the hydatid of Morgagni occurs in boys with a mean age of 10 years and it involves both testes equally, whereas the torsion of testis usually occurs around the age of 13 and is twice more common in the left gonad. Another significant difference between the two conditions is the inflammatory syndrome, which occurs in 45.4% of the children with torsion of testis versus only 18.2% in the torsion of hydatid. Only one out of six testes torted during the neonatal period could be saved (16.6%); the gonad preservation rate was as high as 68.2% in the group of patients with testis torsion occurring outside the neonatal period. These alarming data are accounted for by the non-recognition of the severity of the condition and by the delayed surgical therapy, which occurs on the average 20 hours after the testis torsion has set in. If the asepsis and antisepsis standards are observed, patients with torsion of the hydatid of Morgagni or torsion of testis require neither fluid sampling from the tunica vaginalis for culture, nor antibiotic therapy. **Keywords**: ACUTE SCROTUM, TESTICULAR TORSION, TESTICULAR APPENDAGE, EPIDIDYMO-ORCHITIS.

The acute scrotum syndrome refers to the sudden onset of pain, swelling and other inflammatory phenomena in a hemiscrotum, which may be caused by conditions such as orchiepididymitis, torsion of testis or appendix testis, testicular hematoma due to local injury or hematocele due to adrenal hemorrhage during the perinatal period, testicular tumor, strangulated inguinal or scrotal hernia, acute scrotal edema, Henoch-Schönlein purpura. Strangulated inguinal hernia and testis torsion are surgical emergencies, whereas orchiepididymitis may only require medical therapy. Scrotal injury with hematoma or incarcerated hernia may be diagnosed according to anamnesis, whereas Doppler ultrasound scanning may differentiate the inflammatory phenomena due to orchiepididymitis from the absence of blood flow due to testis torsion (1). A detailed history, through physical examination of the genitalia and

medical imaging examinations such as Doppler ultrasound scanning, and sometimes scintigraphy or IRM, usually allow a preoperative differential diagnosis. Nevertheless, even the slightest diagnosis doubt requires surgical examination designed to rule out testis torsion as the cause of the acute scrotum and to save the gonad (2,3,4). The purpose of this research is to emphasize specific epidemiological aspects in pediatric patients suffering from acute hemiscrotum syndrome, and to review the existing diagnosis and treatment options in a regional Romanian center.

MATERIAL AND METHODS

We have conducted a retrospective analytical study on 257 patients hospitalized and treated in the Pediatric Surgery Clinic of the "Sfânta Maria" Children's Hospital of Iaşi over a period of about 3 years (January 2012 – February 2015). Our hospital is the only tertiary hospital in the Moldova area, which treats pediatric patients coming from 7 counties. The patient data were retrieved from the hospital's computerized database, after entering the disease code N44, which stands for "Torsion of Testis". The system generated 257 patients encoded with this diagnosis, from a total number of 4816 diagnoses. Only 208 of them were eligible for our research, the remaining 49 being excluded as their diagnoses did not correspond to the aim of our study. We carried out an analysis and statistical processing of the patients' demographic data, diagnosis on hospital discharge, age on the first hospitalization, number of hospitalization days, personal history, paraclinical tests and examinations, treatment method, operating technique, subsequent evolution, pathology findings. All patients were seen by at least one specialist doctor, routine complete blood counts, inflammatory tests (ESR, Fibrinogen) and urinalysis were performed. Sometimes, additional examinations were conducted, i.e. abdominal and scrotal ultrasound scanning, Doppler ultrasound scanning and even CT in uncertain cases. The best course of care adopted in our clinic recommends a surgical procedure in all the acute hemiscrotum syndrome cases, in whom suspected testis torsion cannot be ruled out by clinical and paraclinical means, or in whom the painful symptoms due to torsion of the hydatid of Morgagni do not subside within a few hours from hospitalization. The statistical analysis was conducted using SPSS for Windows and Microsoft Excel. The data were reported as means ± standard deviations. The differences between groups were analyzed using the t Student test, and the level of statistical significance was $p \leq 0.05$.

RESULTS

131 of the 208 patients included in the study were finally diagnosed with torsion of the hydatid of Morgagni, 65 with torsion of testis, 10 with acute orchiepididymitis and 2 with post-traumatic scrotal hematoma. Excluding the 16 patients who came in for congenital undescended testicle, which postoperatively proved to be vanishing testis, among the acute scrotum group the testis torsion rate was 25.5%, the rate of torsion of the hydatid of Morgagni was 68.2% and orchiepididymitis 5.2%.

After group analysis, we noted that most of the patients came from urban areas (1.33 ratio). The overall mean age of the patients was 9.66±4.47 years (Fig. 1). 44 of the 65 children finally diagnosed with testis torsion came in for acute scrotum syndrome at a mean age of 13.01±3.93 years, 5 came in immediately after birth and were diagnosed with neonatal testis torsion and 16 patients came in for congenital undes-

cended testicle at the mean age of 3.10±3.00 years; their postoperative diagnosis was vanishing testis. As concerns the mean age on consultation for acute hemiscrotum syndrome, a comparison between the 131 patients with torsion of the hydatid of Morgagni (9.82 years) and the 49 with torsion of testis (11.68 years), reveals a difference of about 2 years, which is statistically significant (p=0.001). The difference increases if we exclude from the second group the five patients who came in during the neonatal period, i.e. 9.82 versus 13.01 years. The torsion of the hydatid of Morgagni occurred on the left side in 67 patients, on the right side in 61 patients and on both sides in 3 patients, whereas the torsion of testis impaired 21 patients in the right side, 42 patients on the left side and 2 patients on both sides.

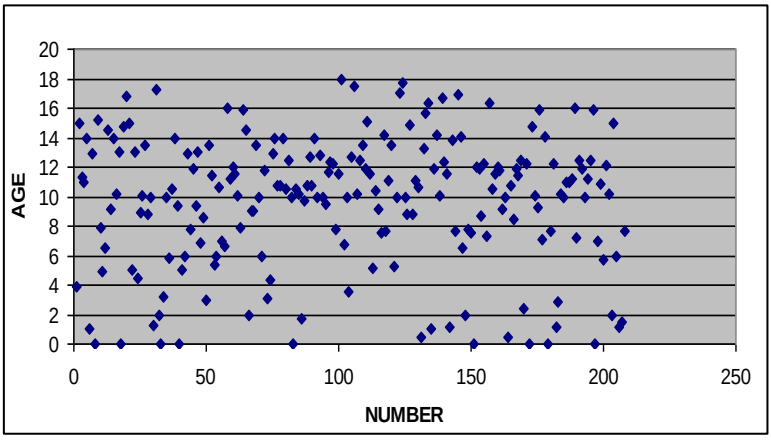

Fig. 1. Distribution of patients by age

The analysis of the personal history of the 131 patients with torsion of the hydatid of Morgagni revealed a prior injury in 7 of them and an intercurrent respiratory condition in 5 other children. Associated conditions were detected in 28 children, 14 of whom suffered from uro-genital conditions. The mean period of time elapsed between symptom occurrence and the patients' seeking medical assistance was 21 hours (between one hour and 7 days). In 44 of the patients the symptoms were edifying, and the doctor on call did not request medical imaging tests, whereas in the other 87 children an abdominal and scrotal ultrasonography was performed. The lab tests revealed an inflammatory syndrome (high leukocytosis, ESR and Fibrinogen levels) in 24 children (18.2%) and nutritional anemia in 9 of them (6.8%). Only three patients were prescribed conservative treatment consisting of bed rest, non-steroidal anti-inflammatory drugs and cold compressions on the aching spot, and they were fully recovered. The other patients underwent surgery under general anesthesia, which consisted of hemiscrotum exploration, removal of the torted hydatid of Morgagni (Fig. 2).

A biopsy of the tunica vaginalis was performed in 9 patients, and fluid was sampled in 55 other patients for culture and antimicrobial susceptibility testing. The culture was negative in all the 55 cases. After the surgery, 59 patients were given antibiotic therapy, namely cephalosporins

or beta-lactams. The postoperative evolution of four patients was marked by the occurrence of a scrotal hematoma, three of whom underwent a second surgery to remove it. Another patient needed a second surgery for postoperative scrotal abscess. The other patients recovered rapidly, and they were discharged, on the average, 2.6 days after the surgery. No pathology tests could be conducted on the removed hydatid of two of the patients due to the fact that the removed mass was too small. In all the other patients, the microscopic examination revealed signs of stasis, inflammation, hemorrhage, hemorrhagic necrosis (Fig. 3).

Fig. 2. Torsion of the hydatid of Morgagni – intraoperative aspect

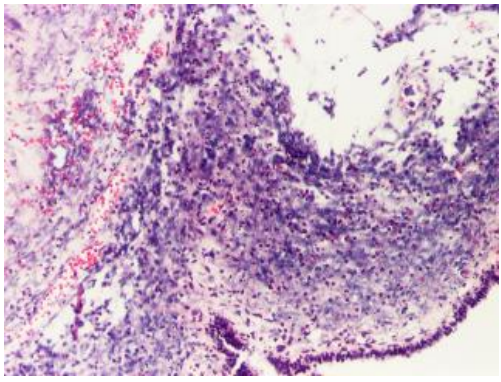

Fig. 3. Hydatid of Morgagni – haemorrhagic necrosis and leukcocytic exudate – HEx100

Three of the 44 patients with torsion of the testis who came in for acute hemiscrotum syndrome outside the neonatal period had suffered prior injury. Associated conditions were detected in 8 children, as 6 of them were also suffering from uro-genital diseases. The mean period of time elapsed between symptom occurrence and the patients' seeking medical assistance was 20 hours (between one hour and 11 days). The lab tests revealed an inflammatory syndrome in 20 children (45.4%) and nutritional anemia in 3 of them (6.8%). Surgery was performed without preoperative imaging tests in only 6 patients, whereas an abdominal and scrotal ultrasonography was performed in the other 38 patients. Since it is not readily available in our hospital, Doppler ultrasonography was conducted preoperatively only in 6 patients, and postoperatively in 10 patients. A pelvic CT scan was performed in an adolescent suspected of testis tumor, but the postoperative pathological examination set the diagnosis of old testis torsion, with total glandular necrosis (Fig. 4). The testis was surgically approached through the scrotum in all the patients, the testis was detorted (between 180° and 1080°), the spermatic cord was injected with xylocaine and, depending on the recoloring degree, the surgeon decided to keep or to ablate the gonad (Fig. 5). Orchiectomy was performed in 7 patients due to the clearly necrotic gonad (the mean period of time before going to see a doctor was 4.4 days for these patients), whereas in other two patients orchiectomy was carried out after 48 hours (on second look). In the other 35 patients, the doctors decided to keep the gonad on condition of its regular ultrasonographic follow-up, and the diseased progressed (one and three-month follow-up) in other 5 patients. As concerns the 14 patients in whom the dis-

ease progressed (31.8%), 7 of the group of 21 were living in rural areas and 7 of the group of 23 were living in an urban environment. Thus, there were no significant differences as concerns the patients' living environment. Overall, after detorting, the three-month follow-up revealed that 30 patients (68.2%) recovered. Orchidopexy was performed on the impaired side in the patients in whom the gonad was preserved, and contralateral orchidopexy was preferred for 7 patients. Two patients required a second surgery, one for the excision of a postoperative hematoma and the other for pus draining. The mean hospitalization duration was 3.7 days for the first surgery.

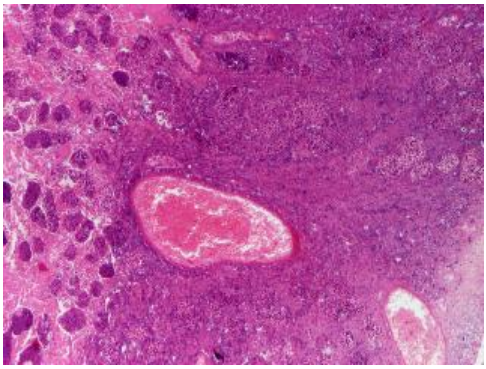

Fig. 4. Testicular torsion - haemorrhagic necrosis – Hex40

Fig. 5. Testicular torsion – intraoperative aspect

Two of the 5 patients with neonatal testis torsion, who came in immediately after birth for acute scrotum suffered from torsion on the right side, two on the left side and one on both sides; orchiectomy was performed in 2 children on the first surgical procedure as there were no doubts about the ischemic necrosis diagnosis, whereas in a patient the gonad was initially preserved but it was finally removed two days later (on second look). Contralateral orchidopexy was also performed in all these patients. The right testis of the child with bilateral torsion was removed on account of the advanced necrosis, whereas his left testis was detorted and fixed, but it later progressed to testicular atrophy. In another patient the testis was detorted and the spermatic cord was injected with xylocaine. The testis was preserved and the 3-month follow-up ultrasonography revealed the patient's recovery. Thus, only one out of six testes could be saved (16.6%).

Fluid was sampled from the testicular vaginal tunic of 29 of all the 49 patients with acute hemiscrotum syndrome due to testis torsion, and the culture was positive in 3 children younger than 6 months; 34 children were administered broad-spectrum antibiotics.

Ten patients, with a mean age of 9.97 years (two newborns, one 5 month infant and 7 children older than 10 years), with acute scrotum syndrome were diagnosed with acute orchiepididymitis intraoperatively. Fluid from the tunica vaginalis was sampled and the result was positive in five of them. All the patients were administered antibiotic therapy. The patients were examined for genitourinary tract abnormalities, detected in 3 of them, and urinary infections, present in two patients. The evolution was poor in a single child with cicatricial phimosis, recurrent urinary in-

fections and postoperative scrotal abscess, who required orchiectomy.

Two boys exhibited right vanishing testis, one suffered from bilateral torsion and 13 suffered from left testis torsion. The congenital undescended testicle was examined by inguinal approach in 9 children and by laparoscopic approach in 7; biopsy of the blind-ending deferent duct was performed in 12 patients (Fig. 6).

DISCUSSIONS

The medical technological breakthroughs achieved lately have led to the decrease of the number of surgical procedures performed in patients with acute scrotum syndrome. Different studies have proven that only 14-38% of the patients with acute scrotum suffered from testis torsion, despite the physical examination and their personal history that would indicate surgery (5). Our research revealed a 25.5% testis torsion incidence rate, a 68.2% Morgagni hydatid torsion incidence rate and a 5.2% orchiepididymitis incidence rate.

Torsion of appendix testis, more precisely of the hydatid of Morgagni and more rarely of the appendix epididymis, is the most common cause of acute scrotum syndrome in children. The hydatid of Morgagni is an embryonic remnant originating in the Müllerian duct, attached to the upper testis pole and occurring in about 90% of the patients. The symptoms evocate an acute scrotum syndrome, the pain sets in progressively, unlike in torsion of testis, and is less sharp, and is sometimes located only in the upper testis pole, where the torted hydatid may be palpated and viewed (blue dot sign). In order to avoid about two thirds of the surgical procedures that are not absolutely necessary each patient should undergo medical imaging tests, more precisely Doppler ultrasound scanning. Ultrasonography sometimes reveals the hydatid as a hypoechogenic mass, which is highly vascularized due to inflammation, and a reaction hydrocele may also occur. The Doppler ultrasound scan may reveal and quantify the blood flow in the testis and the scrotum, and may provide information about the structural integrity of the gonad. The treatment may be conservative and consist of rest, ice packs, scrotum lifting, anti-inflammatory and analgesics. If the diagnosis is uncertain, the pain very sharp or does not subside further to treatment, surgery is recommended for the removal of the necrotic hydatid (6). Unfortunately, since Doppler ultrasound scans could not be performed on the patients hospitalized in our clinic and since there were no well established therapeutic protocols, far too few children could benefit from this examination method and therefore only three of the patients with torsion of the hydatid of Morgagni received conservative treatment, which considerably increased the surgical procedure rate. Nevertheless, this is not a bad approach, since most authors recommend immediate surgery if there is even the slightest doubt

about the diagnosis, all the more so as any medical imaging technique may have false negative results and thus delay the surgical procedure that may save a torted testis (2,3).

Torsion of testis is a surgical emergency that may occur at any age and, if improperly treated, may lead to infertility and psychological impairment. The annual incidence rate of this condition is 1/4000, and about 61% of all the patients are younger than 25 years, and exhibit bimodal age distribution, namely during the neonatal period and around the age of 13 years (7). Our research supports these data, as all the patients younger than 1 year suffered from testis torsion. When comparing the mean age at which the patients came in for acute scrotum, we noted a significant difference of about 3 years between the two groups, namely the 131 patients with torsion of the hydatid of Morgagni (9.82 years) and the 44 patients with torsion of testis (13.01 years). Similar studies have also reported older age of patients with torsion of testis than of patients with torsion of the hydatid of Morgagni (8).

In children, testicular torsion usually occurs in the absence of any predisposing factor, since a prior scrotal injury or intense physical effort was only reported in 4-8% of the cases (9). In our case, a prior injury was reported only in 5.3% of the children with torsion of the hydatid of Morgagni and in 6.8% of the children with testis torsion. Other possible triggering factors are the sudden testis volume increase during puberty, congenital undescended testicle, testicular tumors, low temperatures associated with an exaggerated cremasteric reflex, presence of a long intrascrotal spermatic cord (9). Whereas appendix testis torsion seems to affect both sides equally (27 left versus 21 right), left side impairment by torsion of testis was twice more common than right side impairment, which was also reported by other literature studies (8). Another significant difference between the two conditions is the occurrence of the inflammatory syndrome in 45.4% of the children with torsion of testis versus 18.2% in those with torsion of hydatid. Other studies also suggested that leukocytosis and the NLR (neutrophil to lymphocyte ratio) are predictive of inflammatory processes and also torsion of testis (10,11).

Detorting during the first 6 hours is associated with over 90% chances of saving the testis, whereas the same procedure applied more than 24 hours from the event only saves less that 10% of the testes (12). Surgery is sometimes delayed due to lack of medical education, to children living in disadvantaged families who do not seek medical assistance, to long distances to the nearest hospital or sometimes to the failure of the first doctor who examines the child to recognize the condition. In our research, the mean period of time elapsed between symptom occurrence and the patients' seeking medical assistance was 21 hours for children with torsion of the hydatid of Morgagni and 20 hours (between one hour and 11 days) for those with torsion of testis, which explains the testicular preservation rate of only 68.2%. In our research, the patients' living environment did not influence in any way their postoperative evolution. The surgeons usually decides whether to preserve or remove the gonad during the surgical procedure, depending on the time elapsed from symptom occurrence, on the degree of torsion, on the color of the testis after detorsion, and possibly after the spermatic cord has been injected with xylocaine. If the black-purplish color persists, this indicates irreversible glandular necro-

sis and recommends removal, whereas if the testis becomes pink again, it should be preserved and orchidopexy should be done. The torted testis preservation rate varies between 58 and 75.7% in various studies (13,14). Most authors recommend bilateral orchidopexy after detorsion, in order to prevent any reoccurrence (15), but in the absence of therapeutic protocols this was not complied with throughout our study. Orchidopexy is done by fastening the testis against the scrotal wall using two or three suture points with nonabsorbable stitches crossing the tunica albuginea. Although it has been argued that this technique may trigger the production of antispermatic antibodies, this has not been accurately proven and, at any rate, the torsion reoccurrence risk seems higher (16).

Originally described by Taylor in England, in 1897, and then 50 years later by Campbell in North America (17,18), perinatal testicular torsion is rare yet controversial event as to its etiology, clinical form, management and long-term sequelae. Perinatal testicular torsion includes antenatal torsion and torsion occurring during the first 30 days after birth, and it makes up about 12% of testis torsions in children (10.2% in our research). The possible etiopathogenic theories include difficult delivery, breech presentation, multiparity, high birth weight and exaggerated cremasteric reflex (19). Prenatal torsion has minimum clinical symptoms and no discomfort, whereas postnatal torsion has significant clinical symptoms, such as pain and acute inflammatory phenomena in a previously healthy testis. Since antenatal ultrasonography does not have high sensitivity to this abnormality, antenatal torsion is usually detected on the routine newborn checkup and it is usually too late to save the gonad. Therefore, the management of this condition is highly controversial. Some authors only recommend clinical and ultrasound monitoring and avoidance of surgical procedures, whereas others suggest immediate scrotal or inguinal exploration and contralateral orchidopexy (20). According to other authors, if the torsion occurs much before the birth (the inflammatory signs on the hemiscrotum are discrete), surgery can wait and the patient may receive conservatory treatment or elective orchiectomy and contralateral orchidopexy will be done; if the torsion occurs at birth or after birth, surgery is a major emergency and is to be done even in the absence of any medical imaging tests (21). The advocates of conservative treatment rely on the low incidence of contralateral torsion and support the avoidance of any anesthetic and surgical risks during the neonatal period. Moreover, if the parents are correctly informed, they will bring the child to the emergency room on the first signs and symptoms of torsion of testis, which means that surgery may be done on time. In a study conducted on 48 cases of bilateral perinatal testicular torsion, despite the prompt surgical intervention in 46 of these patients, only 3 testes exhibited a blood flow on postoperative Doppler ultrasonography (20). In our research, only one patient exhibited signed of recovery at the three-month follow-up, and the gonad had to be removed due to advanced necrosis in all the other cases.

If the asepsis and antisepsis standards are observed, patients with torsion of the hydatid of Morgagni or torsion of testis confirmed and surgically treated require neither fluid sampling from the testicular vaginal tunic for culture, nor antibiotic therapy. Nevertheless, fluid was sampled from the tunica vaginalis of 55 patients with torsion of the hydatid of Morgagni, for culture purposes, and the results were

negative in all these cases; furthermore, 59 patients were administered intravenous antibiotic therapy. Only one patient living in a disadvantaged social environment and who did not observe the postoperative hygiene requirements developed a scrotal abscess 5 days after the surgery and required a second surgical procedure. As for the patients with torsion of testis, only 3 of the 30 samples collected were positive, all three in infants under the age of 6 months; on the other hand, 34 patients were administered broad-spectrum antibiotic therapy. In our opinion, according to these data, fluid sampling from the testicular vaginal tunica is only necessary for patients with orchiepididymitis or strong inflammatory phenomena. Prophylactic antibiotic therapy is recommended only to infants with acute scrotum who underwent surgery.

Orchiepididymitis is the most common cause of acute scrotum syndrome after puberty, with an incidence peak at the age of 40-50 years, but it may also occur in babies. In our research, the incidence rate of this condition was 5.2% versus 9% or 16% in other studies, which also included patients older than 18 years (8,22), and the disease affected two categories of patients, namely neonates and adolescents. Surgery was performed in all the patients, who were administered antibiotic therapy. The evolution was positive in 9 out of 10 cases. The most common etiology is urinary tract infection related to possible associated malformations, hematogenous infection or scrotal injury. The treatment is conservative if we are absolutely certain about the diagnosis and it consists of analgesics, anti-inflammatory drugs, ice pack and antibiotic therapy, under ultrasound scanning and biological monitoring. Nevertheless, if there is even the slightest doubt surgery is to be done in order to rule out testis torsion as a cause of acute scrotum.

CONCLUSIONS

Torsion of the hydatid of Morgagni occurs in boys at the approximate age of 10 years and it affects both testes equally, whereas torsion of testis usually occurs at the age of 13 and affects twice more often the left gonad. Another significant difference is the inflammatory syndrome, which occurs in 45.4% of the children with torsion of testis versus only 18.2% of those with torsion of hydatid. Only one out of six torted testes could be saved in the neonates (16.6%), whereas in the group of patients with torsion of testis that were not neonates, the gonad preservation rate was 68.2%. These data are accounted for by the non-recognition of the severity of the condition and by the delayed surgical therapy. Patients with torsion of the hydatid of Morgagni or torsion of testis require neither fluid sampling from the tunica vaginalis for culture, nor antibiotic therapy.

A CASE OF POLYMYOSITIS WITH INTERSTITIAL LUNG DISEASE ONSET (Abstract): Polymyositis is an idiopathic inflammatory myopathy of unknown aetiology that affect skeletal muscles causing symmetrical, proximal muscle weakness, and also other internal organs. The investigations reveal elevated skeletal muscle enzyme levels and characteristic electromyography (EMG) and muscle biopsy findings. Pulmonary involvement in polymyositis includes respiratory muscle weakness, aspiration pneumonia, interstitial lung disease, infection and drug-induced pneumonia. We expose the case of a young woman (47 years old) who presented to the Pulmonology Clinic with fever, cough, purulent sputum, discrete myalgia, being diagnosed at that moment with interstitial lung disease and treated with antibiotics, low dose of corticosteroids and symptomatic drugs. The evolution was slowly favorable for the respiratory impairment, but the patient developed exacerbated myalgia, muscle weakness, reaching even the impossibility of maintaining orthostatism, and also joint pain. Biological investigations revealed an important hepatocytolysis syndrome and also increased levels of muscle enzyme. The hypothetical diagnosis was polymyositis and to sustain this theory it was performed a muscle biopsy. The patient was transferred afterwards to the Rheumatology Clinic, in order to perform other specific investigations. In our clinic the patient maintained elevated levels of skeletal muscle enzymes and the muscle biopsy revealed polymyositis findings. Also immunological investigations objectified the presence of Jo1 antibodies. Therefore we pleaded for the diagnosis of idiopathic polymyositis, acute form. A multidisciplinary approach is needed in order to establish an accurate diagnosis and to institute a proper treatment. **Keywords:** POLYMYOSITIS, INTERSTITIAL LUNG DISEASE, MUSCLE ENZYME.

The inflammatory myopathies are a heterogeneous group of subacute, chronic, or acute acquired diseases of skeletal muscle. The muscle biopsy identifies an inflammatory infiltrate that, according to its localization and distribution, decidedly contributes to diagnosis. Specialty literature reveals three entities: dermatomyositis, characterized by a specific rash which precedes muscle weakness; polymyositis, with muscle weakness, symmetrical and diffuse, involving the proximal muscles of the neck, shoulders, trunk, hips and thighs and inclusion body myositis (1). Therefore polymyositis is an idiopathic inflammatory myopathy of unknown aetiology that evolves over weeks to months,

affecting adults, rarely children. It's pathognomonic manifestation is represented by symmetrical, proximal muscle weakness. The internal organs are also affected (2). Pulmonary involvement in polymyositis includes respiratory muscle weakness, aspiration pneumonia, interstitial lung disease, infection and drug-induced pneumonia (3). There are cited in literature several cases in which interstitial lung disease represents the onset of polymyositis, the diagnosis in those cases being much harder to establish (4,5,8).

The clinical diagnosis is confirmed by elevated levels of muscle enzyme, the most sensitive being creatine kinase. Also the biological investigations reveal an important hepatocytolysis syndrome and increased levels of lactate dehydrogenase and aldolase (2,6).

By far, the investigation which establishes the accurate diagnosis is muscle biopsy. The specific findings are represented by inflammation and multifocal lymphocytic infiltrates surrounding and invading healthy muscular fibers. In chronic stages connective tissue is increased and reacts with alkaline phosphate (6,7).

CASE REPORT

We expose the case of a young woman (47 years old) that was admitted to the Pulmonology Clinic for fever, cough and purulent sputum and discrete myalgia. The symptomatology had appeared about one month prior to admission. The patient had a history of chronic obstructive pulmonary disease, arterial hypertension and depression. She was a stay-at-home mother, did not smoke or drink and she lived in a rural household.

Clinical examination revealed an influenced general state, with depressive facies, sweaty skin. Pulmonary auscultation objectified crackles disseminated both lung fields.

Biologically the patient presented an important hepatocytolysis syndrome (ASAT=628U/l, ALAT=406U/l), elevated level of lactate dehydrogenase (1187 U/l), inflammatory syndrome (ESR= 20mm/1h, CRP= 48mg/l), with decreased levels of serum proteins (46g/dl).

Chest radiography revealed the presence of infiltrative-nodular opacities on both lung fields, without systematized condensation (fig.1). Bacteriological sputum exam was negative for BK.

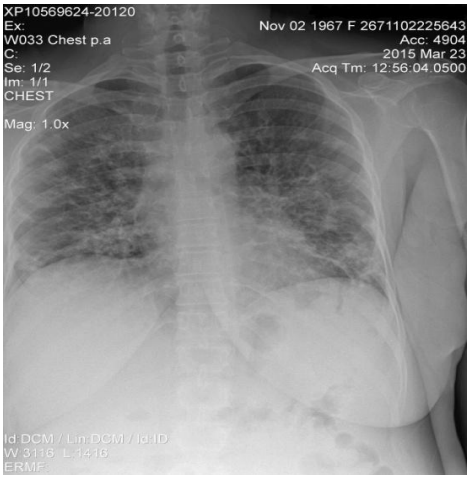

Fig. 1. Aspect of interstitial lung disease on chest radiography.

Corroborating clinical examination, radiological and biological investigations this leads to the establishing the diagnosis of interstitial pneumonia and the patient was treated with antibiotics (Ceftriaxone), low dose of corticosteroids (Prednisone 40mg daily) and symptomatic drugs (to treat fever and pain).

The evolution was slowly favorable for the respiratory impairment, but the patient developed exacerbated myalgia, muscle weakness, reaching even the impossibility

of maintaining orthostatism, and also joint pain. The hypothetical diagnosis was polymyositis and to sustain this theory it was performed a muscle biopsy. The patient was transferred afterwards to the Rheumatology Clinic, in order to perform other specific investigations.

In the Rheumatology Clinic the patient maintained elevated levels of transaminases (ASAT= 375U/l, ALAT= 351U/l), inflammatory syndrome (CRP= 26,03mg/l), increased level of lactate dehydrogenase (1670U/l) and hyposideremia (34 µg/dl). Also the value of creatine kinase was elevated (3013U/l). Anti HCV antibody and Ag HBs was negative, rheumatoid factor also negative. Urine analysis was pathologic with urine culture positive for *Klebsiella* spp.

Musculoskeletal examination objectified the impossibility of maintaining orthostatism and muscular testing revealed MRC= 3-4 for the proximal muscles of upper limbs , MRC= 1 for proximal muscles of legs and MRC= 1-2 for cervical muscle. The patient also presented pain on palpation of topographic points of the knees.

The muscle biopsy revealed polymyositis findings with inflammation and multifocal lymphocytic infiltrates surrounding and invading healthy muscle fibers (fig.2).

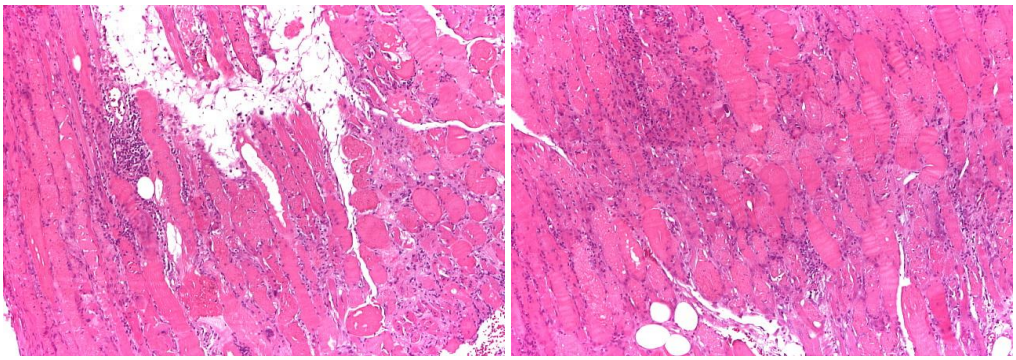

Fig. 2. Polymyositis findings at the muscle biopsy; HE, magnification x40.

Also the immunological investigations revealed the presence of Jo1 antibody, which are pathognomonic for polymyositis with interstitial lung disease onset. It was took into consideration also a paraneoplastic syndrome, but the abdominal-pelvic ultrasound was normal.

Clinical manifestations, biological and immunological investigations as well as the aspect of muscle biopsy pleaded for the diagnosis of idiopathic polymyositis, acute form.

The treatment administrated in hospital was represented by corticosteroids, first in pulse therapy for three days (Solumedrol 1g daily), then Prednisone 1 mg/kgc daily, antibiotics (Ciprofloxacin 200mg/12h), proton pomp inhibitor, symptomatic drugs and kinetotherapy.

The evolution was slowly favorable with decrease in dynamics of transaminases, lactate dehydrogenase, creatine kinase (tab. I) and slight improvement in muscle weakness. Home treatment was represented by immunosuppressive drugs (Azathioprine 100 mg daily), proton pomp inhibitor, Prednisone 75 mg daily, vitamin D and calcium. It was made the recommendation to return in the Rheumatology clinic in one month for biological investigations.

TABLE I
The evolution of biological investigations.

	03.04.2015 (Iaşi)	15.04.2015 (Iaşi)	17.05.2015 (Tulcea)	06.07.2015 (Iaşi)	17.07.2015 (Iaşi)
ALAT	351 U/L	265 U/L	24U/l	31U/l	31U/l
ASAT	375 U/L	134 U/L	33U/L	34 U/l	35U/l
LDH	1670 U/L	1217 U/L	-	686 U/l	676 U/l
CK	3073 U/L	1478 U/L	262U/L	254 U/l	97 U/l

In July the patient returned in the Rheumatology clinic with discrete myalgia, clinical examination revealing a significant improvement of muscle testing (MRC=5). Biologically the patient presented normal values of transaminases, CK and lactate dehydrogenase with decreased values (tab. I).

DISCUSSIONS

Pulmonary involvement in polymyositis includes interstitial lung disease, infection favored by respiratory muscle weakness or drug-induced pneumonia (3).

Interstitial lung disease may be the onset of polymyositis, the motive of attention. Polymyositis may have this onset mainly when the immunological investigations reveal the presence of Jo1 antibodies and clinical manifestations include arthralgia. Jo-1 antibodies represent an important marker of a clinical syndrome characterized by inflammatory myopathy, interstitial pneumonitis, arthritis, fever, Raynaud's phenomenon. This form of respiratory affection do not seem to worsen prognosis (1, 9, 10).

One of the particularities of the case that we presented is the unusual onset of polymyositis, with interstitial lung disease, which made the diagnosis much difficult to establish. Also, initially, the patient was undertreated with corticosteroids (Prednisone 40 mg daily to a patient weighing 90 kilograms), in absence of a certain diagnosis, which allowed to exacerbate the musculoskeletal manifestations reaching even the impossibility of maintaining orthostatism.

CONCLUSIONS

We presented this case report in order to highlight the idea that interstitial lung disease may be a first sign, a first manifestation of polymyositis. The clinician should remain alert to potential muscular or cutaneous symptoms and forms of connective tissue disease whenever a pathological diagnosis of nonspecific interstitial pneumonia is made.

PARADOXICAL SPHINCTERS IN THE ABDOMEN AND A POSSIBLE G.E.R.D. CURE

Nitric oxide molecules serve as neurotransmitters to relax smooth muscle tension in many parts of the body. They play an important role for correct smooth muscle function in unusual locations. Cells producing nitric oxide can be found in the gastric fundus, the anorectal continence organ, vesicourethraltract and also in the uterine cervix in the final trimester of pregnancy. In all these locations they serve as elements of anatomical sphincter structures that have a paradoxical function. As an example, the lower esophageal sphincter (LES) represents a variation of circular muscular occlusive mechanisms found elsewhere in the gastrointestinal tract. The LES is a double layer stretch sphincter that operates in an apparently paradoxical manner: it closes when under stretch and opens when the muscle fibers contract. All traditional forms of operative treatment of gastroesophageal reflux disease (GERD) impede the natural functioning of the stretch sphincter to a greater or lesser degree by locking it up. The cause of GERD is mainly by contraction of the esophagus brought about by the cephalad transposition of the stretch sphincter segment into the chest (an incipient axial hernia - frequently undiagnosed in early stages). The operative repositioning of the stretch sphincter segment into the abdominal cavity provides sufficient restoration of the natural topographic relationships to achieve a cure of GERD. In particular, high-resolution esophageal manometry of the lower esophageal sphincter can easily detect every functional disturbance caused by gastric plication. (Stelzner F. Paradoxical sphincters in the abdomen. *Der Chirurg*. Doi:10.1007/s00104-015-0029-5, 20.06.2015, 86:8:761-770)

Department of Surgery

CURRENT TREATMENT OF DIABETIC MACULAR EDEMA (Abstract). Diabetic macular edema is the main cause of vision loss in developed countries among working people. Laser photocoagulation was the mainstay of treatment for many years, but it could only preserve visual acuity, and not increase it. The anti-VEGF (Vascular Endothelial Growth Factor) agents proved their efficacy in reducing macular thickness and increasing visual acuity, although a minority of patients (30 %) achieved good visual acuity (20/40). Corticosteroids were most effective in reducing macular edema, but this reduction in macular thickness did not correlate with the level of visual acuity. They were associated with secondary cataract and glaucoma. **Keywords**: DIABETIC MACULAR EDEMA, LASER, ANTI-VEGF, CORTICOSTEROIDS.

Diabetic macular edema is a complication of diabetic retinopathy which involves the central part of the retina (macula) and it is the main cause of vision loss in developed countries among working people (1). This is why the socioeconomic consequences of this disease are very important, with significant implications for patients and healthcare providers (2).

Diabetic macular edema appears after the break-down of the blood-retinal barrier. Its incidence is directly correlated with the duration of diabetes and with poor glycemic control (3).

Chronic hyperglycemia produces a multifactorial cascade of biochemical processes including increased capillary permeability, activation of cytokines and inflammation, blood flow alteration. Vascular endothelial growth factor (VEGF), especially A-isoform, is a major factor in the stimulation of inflammation and also in angiogenesis (4). Hypoxia caused by microvascular alterations stimulates the production of VEGF to improve the capillary perfusion.

Neuronal dysfunction induced by hyperglycemia can also contribute to the drop of vision (5). Early diabetic neuropathy can be evaluated by Neuropad® test (6).

The aim of this review is to present the conclusions of the most important studies in the literature regarding this condition. Included in the analysis were only the prospective, comparative and randomized trials which included laser treatment, anti-VEGF agents and corticosteroids with a minimal follow-up of 6 months.

Laser photocoagulation

Laser photocoagulation was the main-

stay of treatment for diabetic macular edema. This was the conclusion of 2 major clinical trials: Diabetic Retinopathy Study and Early Treatment Diabetic Retinopathy Study (ETDRS).

Although photocoagulation was efficient in preserving visual acuity, it did not succeed to increase it. Patients with perifoveal ischemia are not considered eligible for this kind of therapy. Laser treatment can reduce the risk of moderate visual loss (defined as a drop of 3 lines on the visual acuity chart), by 50% but only 3% of the patients presented an increase in visual acuity (7).

Recent studies proved that laser photocoagulation resulted in an over 10 letter improvement in visual acuity in 7% to 31% of the cases (8).

This type of treatment for diabetic macular edemaalso has side effects. Foveal burns, visual field defects, subretinal fibrosis were reported after photocoagulation (9).

Despite aggressive treatment, some patients suffered a severe visual loss after the laser treatment (10).

Intravitreal anti-VEGF agents

Ranibizumab was the agent most frequently used in studies. There are 9 trials investigating the effect of this anti-VEGF agent in the treatment of diabetic macular edema.

Ranibizumab for Edema of the mAcula in Diabetes (READ) 2 was the first important randomized clinical trial which compared the intravitreal injections with laser photocoagulation. After 6 months, the group treated with Ranibizumab visual acuity was significantly better than in the group treated with laser. Also, the addition of laser after Ranibizumab did not provide additional functional benefits (11).

Ranibizumab Monotherapy or Combined with Laser versus Laser Monotherapy in Asian Patients with Diabetic Macular Edema (REVEAL) was a similar study. It included 3 groups of patients who were treated with Ranibizumab, laser, or the combination Ranibizumab plus laser.

After 12 months of follow-up the results were better for the groups who received intravitreal injections in terms of improved visual acuity (12).

In the *Ranibizumab monotherapy or combined with laser versus laser monotherapy for diabetic macular edema* (RESTORE) study the patients were also randomized to laser, Ranibizumab, and combined treatment. The results were analyzed after 12 months.

The group who received Ranibizumab had the best-corrected visual acuity. After 24 months of follow-up the outcomes were similar to those after 1 year of treatment (13).

These two studies proved a statistical significant improvement of visual acuity for the Ranibizumab patients compared to those who received laser treatment, especially when the variable analyzed was the proportion of patients who gained more than 15 letters on the visual acuity chart.

Ranibizumab Injection in Subjects With Clinically Significant Macular Edema (ME) With Center Involvement Secondary to Diabetes Mellitus (RISE and RIDE) studies were identical in design. They compared 2 doses of Ranibizumab (0.3 mg and 0.5 mg) with sham. After 24 months the proportion of patients who gained more than 15 letters was higher in the 0.3 mg group in RISE study, and in the 0.5 mg group in RIDE study. Both clinical trials showed better functional outcomes with Ranibizumab than with sham (14).

Ranibizumab for Edema of the Macula in Diabetes (READ 3) is another study which compared the outcomes of a high dose Ranibizumab (2 mg) with the standard dose (0.5 mg). After 6 months no statistically significant differences in visual acuity were found between the 2 groups (15).

Another study, published only in abstract form, compared monthly intravitreal injections with Ranibizumab (0.5 mg) versus Bevacizumab (1.5 mg). After 48 weeks, no statistically significant differences were found between the groups (16).

The Diabetic Retinopathy Clinical Research Network (DRCRN) study, conducted by Elman (17), compared the efficacy of Ranibizumab plus prompt laser (3 to 10 days after the injection) or deferred laser (after 24 weeks) with sham injections plus prompt laser or Triamcinolone (Trivaris) plus prompt laser. After 1 year, the groups who received Ranibizumab had better visual acuity compared to those treated with laser or Triamcinolone. After 2 years of follow-up the proportion of patients who gained more than 10 letters was not statistically different between the Ranibizumab plus prompt laser group compared to laser group, but there was a statistically significant difference between laser and Ranibizumab plus deferred laser. The authors of the study did not have an explanation for this fact.

Bevacizumab proved its efficacy in the treatment of diabetic macular edema in several prospective studies. The most well-known is *Bevacizumab or Laser Therapy in the Management of Diabetic Macular Edema* (BOLT) study (18) which compared the intravitreal injections of Bevacizumab (1.25 mg) with laser photocoagulation. After 24 months of follow-up visual acuity was higher in the Bevacizumab group; also the proportion of patients who gained more than 10 letters was higher in the group treated with intravitreal injections.

Lam (19) compared 2 doses of Bevacizumab (1.25 mg versus 2.5 mg) for the treatment of diffuse diabetic macular edema. After 6 months, there was an improvement of visual acuity in both groups compared to baseline, but there was no difference between groups. The patients received 3 intravitreal injections during this period.

Four clinical trials investigated the combination of Triamcinolone and Bevacizumab.

Soheilian (20) compared 3 groups of patients with diabetic macular edema: the first group was treated with Bevacizumab, the second with laser photocoagulation, and the third with Bevacizumab plus Triamcinolone.

After 36 weeks, the visual acuity improved more in the bevacizumab group than the other two groups, although the difference was not statistically significant. After 24 months there were not statistically differences between the groups.

Intravitreal Bevacizumab with or without Triamcinolone for refractory diabetic maculat edema (ATEMD) study (21) included 3 groups of patients treated with Bevacizumab, Triamcinolone, and combined treatment, respectively. The outcomes were similar after 6 months.

Lim (22) studied the combination of Bevacizumab and Triamcinolone and compared it with Bevacizumab and Triamcinolone alone. No differences in best-corrected visual acuity or macular thicknessbetween the groups were found after 12 months of follow-up.

Another study, conducted by Ahmadieh (23), compared 3 groups of patients with

diabetic macular edema who did not adequately respond to laser. Group I was treated with Bevacizumab (3 injections of 1.25 mg every 6 weeks) plus Triamcinolone (a single 2 mg injection), group II received Bevacizumab (administered in the same manner as in group I), and group III received sham injection. The visual acuity improved more in the first2 groups compared to sham group, but there were not statistically differences between Bevacizumab group and the group on combined therapy.

Pegaptanib was studied only in two trials. Both studies compared this anti-VEGF agent with sham treatment.

Cunningham (24) conducted a study which compared 3 doses of Pegaptanib (0.3, 1 and 3 mg) with sham in patients who did not receive previous laser treatment. After 6 months, the first 2 groups had better functional outcomes than the 3 mg Pegaptanibor sham groups.

The second clinical trial, reported by Sultan (25) in 2011, compared the efficacy of Pegaptanib with sham. After 2 years of follow-up, visual acuity was significantly better in the treated group than in the sham group, but there was no difference in the proportion of patients who gained more than 10 letters.

Aflibercept is the newest anti-VEGF agent available and its efficacy in treating diabetic macular edema was proven by the Da Vinci trial (26). That study compared laser treatment with several doses of Aflibercept, and the functional outcomes were better for the anti-VEGF agent after 6 months. The best regimen proved to be 2 mg every 4 weeks.

The main complication after intravitreal injections is endophthalmitis. Because of the continuously increasing numbers of intravitreal injections that are performed worldwide, it has become the main cause of endophthalmitis.

Corticosteroids

Dexamethasone was studied in 2 important trials.

Haller (27) compared 2 doses of Dexamethasone (350 and 700 μg), administered as an intravitreal implant, with no treatment. After 3 months, only the patients who received 700 μg gained more than 10 letters in visual acuity. This difference was statistically significant (33% versus 12%). The 350 μg group showed a non-statistically significant improvement compared to laser.

After 6 months of follow-up there were no differences between the treated groups and the non-treated group. Dexamethasone had a maximum effect after 3 months, but the efficacy began to decline after that.

The second trial, by Callanan (28), included 2 groups of patients: one treated with laser, the other with laser plus Dexamethasone. Although in the first months better results were noticed in the Dexamethasone group, after 12 months of follow-up the authors did not find any differences between the groups.

Fluocinolone is another corticosteroid which was studied (as an intravitreal implant) for the treatment of diabetic macular edema. The *Fluoconolone Acetonide in Diabetic Macular Edema* (FAME) study (29) compared 2 doses of Fluocinolone (0.2 and 0.5 μg/day) with sham intravitreal injections in patients who had at least one laser treatment before being included in the study. After 24 months visual acuity was significantly better in the corticosteroid groups compared to sham. The differences between the 2 groups on Fluocinolone were

not significant.

Pearson (30) compared Fluocinolone with laser treatment. After 3 years, there was no difference between the groups regarding the proportion of patients who gained more than 15 letters in visual acuity.

Triamcinolone was evaluated in several comparative studies as intravitreal injections. The trials that included patients treated by laser and patients who received Triamcinolone showed better results for the laser groups (31). Ranibizumab was also superior to Triamcinolone, and the differences reached a statistical significance level.

The main complications of corticosteroids are cataract and glaucoma. Their incidence is directly dose-related. The biodegradable intraocular implants that release the corticosteroid in a controlled manner seems to have a better safety profile and an efficacy that is comparable to the anti-VEGF agents. In a recent study, published in Ophthalmology in February 2015, it is suggested that the first line of treatment should be the anti-VEGF agent for the phakic eyes and the biodegradable implant with Dexamethasone for the pseudophakic eyes.

CONCLUSIONS

In our opinion, the anti-VEGF agents proved their efficacy in treating diabetic macular edema. Ranibizumab was the most used agent in clinical trials. It is superior to laser, but the results of the different studies must be analyzed with moderation, because half of the patients will not have a driving vision.

Corticosteroids produced a more significant reduction in macular thickness compared to laser or anti-VEGF agents, but they were associated with secondary cataract and glaucoma.

Despite a wide spectrum of possibilities for treating diabetic macular edema, only a minority of patients achieve good vision (20/40), so future studies should bring new therapies for treating this condition.

ACKNOWLEDGEMENTS

This study is done under the frame of European Social Fund, Human Resources Development Operational Program 2007-2013, project POSDRU/159/1.5/S/133377, "Excellence program in doctoral research and multidisciplinary postdoctoral in chronic diseases".

NEWS

INFLAMMATORY HEPATOCELLULAR CARCINOMA

Hepatocellular carcinoma (HCC) is the fifth most common cancer worldwide. The incidence is increasing because of the increasing prevalence of chronic liver disease, both viral and metabolic. Uncommonly, HCC occurs in patients without cirrhosis. Lymphoepithelioma-like carcinoma (LELC) is defined as a tumor composed of large undifferentiated epithelial cells with a predominant lymphoplasmacytic component. These tumors are reported to occur in several organs, including nasopharynx, salivary glands, lungs and stomach and also have been uncommonly reported in trachea, lacrimal glands, ureters, urinary badder, uterine cervix, vagina, ovaries, breast, soft tissue, and skin. Epstein-Barr virus (EBV) has been shown to be strongly associated with LELCs of the nasopharynx, stomach, salivary glands, lungs, and thymus in the form of integration of the viral genome in the tumor cell nuclei. However, this association has not been shown in LELCs of the urinary bladder, uterine cervix, or skin. Regardless of EBV status, the morphologic features and prognosis are the same, except for the uncommon sites where the prognostic information is limited. Human papilloma virus (HPV) DNA has been shown in the tumor cells of lymphoepitheliomas of the breast, and transcriptionally active HPV has been shown by in situ hybridization in LELCs of the oropharynx. There is controversial evidence of involvement of HPV in the uterine cervix; some authors report its presence, whereas others do not. The World Health Organization has recently recognized LELC, or inflammatory HCC (i-HCC), as a variant of HCC. To date, LELCs of the liver have been reported in the form of cholangiocarcinoma (n ¼ 20) and HCC (n ¼ 9), with only 1 lymphoepithelioma-like HCC (LEL-HCC) being positive for EBV. The authors studied all cases of LELC of the liver of the institution from the past 23 years, by analyzing for the expression of p16 protein or the presence of HPV. They characterized the immunophenotype of the inflammatory cells within the tumors, the epithelial differentiation pattern of the tumor cells, features of the background liver, and the viral status of the tumor cells. All of the cases were HCC that arose in noncirrhotic livers, two showed biphenotypic differentiation, and none were positive for EBV or HPV (Patel KR, Liu TC, Vaccharajani N, et al. Characterization of Inflammatory Hepatocellular Carcinoma. Arch Pathol Lab Med. 2014;138:1193–1202).

CLINICAL AND PARACLINICAL ASPECTS OF EBSTEIN'S ANOMALY – SEVERE FORM IN NEWBORNS (Abstract): Ebstein's anomaly is a rare heart malformation, with a broad spectrum of anatomic abnormalities, leading to different clinical, electrocardiographic, echocardiographic changes and a reserved prognosis. We have described a case of an infant diagnosed with Ebstein's anomaly – a severe form. **Keywords:** EBSTEIN'S ANOMALY – SEVERE FORM, PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA

Ebstein's anomaly is a congenital malformation of the tricuspid valve in which septal and posterior valves are not attached to the tricuspid annulus, having a spiroid line, shifted to right ventricle apex; and the anterior foil is usually malformed, abnormally attached or adherent to right ventricle. The prevalence of disease is of 5.2 to: 100,000 newborns, representing 0.5% of MCC (1, 2, 3).

The control studies that have been conducted so far suggest the involvement of anomaly more frequently in twins, in children with a family history of MCC and whose mothers were treated with benzodiazepines (6).

80% of patients with Ebstein's anomaly can also develop interatrial communication (7, 8) through which right-to-left shunting of blood that can occur are right-left blood, and 20%: bicuspid aortic coarctation of the aorta, aortic valve atresia, atresia or pulmonary hypoplasia, mitral valve prolapse.

The severity of hemodynamic disorders in patients with Ebstein's anomaly depends on the degree of movement and functional status of the tricuspid valve foils. In patients with minimal apical displacement of tricuspid foils, valvular function is normal; while patients with severe displacement foils or abnormal tricuspid valve attachment have an increased pressure in AD and right-to-left interatrial shunting (5).

We will discuss the clinical, electrocardiographic, echocardiographic features and therapeutic management of a newborn diagnosed with Ebstein's anomaly.

CASE REPORT

We will present the case of a male infant aged 11 days, which is hospitalized by clinical transfer with generalized cyanosis, polypnea, tachycardia and the investigation revealed a systolic murmur detected in maternity.

Family history: the infant is the third

child of an apparently healthy couple; mother aged 31 yrs. and father aged 40 yrs. There are no cases of congenital anomalies or genetic disorders in the family.

Personal physiological history: Pregnancy was assessed 5 times by the family physician; mother was admitted to hospital for premature impending birth at 32 weeks. Birth was full term, natural assisted by medical staff in the ambulance, birth weight: 3,400 g, neonatal hypothermia (35.3˚C)

Pathological personal history: Diagnosis of neonatal hypoglycemia, maternofetal infection and congenital heart malformations is made in the neonatology department.

Clinical history at admission: General poor state, cyanotic elastic skin, cold extremities, FA-3/4 cm normotensive, normal chest, symmetrical rib excursion, tachypnea 45/min, SaO_2(-):70%, SaO_2(+):98%, rough MV, without over-added rales, chest area normally conformed, tachycardic rhythmic heart sounds, AV=160/min, systolic murmur degree III / 6 in II intercostal left space. BP right upper limb: 67/47 mmHg, BP right leg 65/41 mm Hg, liver at 2 cm below costal margin, abdomen depression, bowel movements and physiological urination.

Cardio-thoracic radiography shows a global cardiomegaly ICT=0.7, normal pulmonary transparency and free cisto-diafragmatic sinuses (fig.1).

The electrocardiogram shows sinus rhythm of 140/min, electrical axis to the right (+120 degrees), right atrial overload (where P is high, sharp in DII, DIII), major block of right bundle branch (prolongation of QRS=180 msec in pericordial leads) with secondary repolarization changes, BAV degree I (PR interval elongated PR=210 msec) (fig.2).

Fig. 1. Cardio-thoracic radiography global cardiomegaly

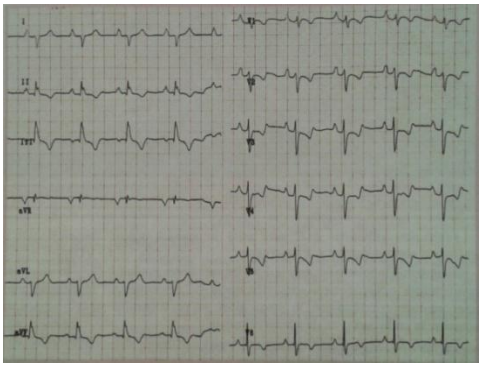

Fig. 2. Electrocardiogram RS 140/min BRD, BAV

Transthoracic echocardiography was the chosen method for the diagnosis of Ebstein's anomaly; there are right cavities with increased volume, SIV paradoxal movements. Apical 4C, there appears the apical displacement of the tricuspid septal insertion foil 5.3/5.5 mm/m^2 body surface area, VD degree of atrialization is over 80%, with compression of the left ventricle, intrarial septal discontinuity, type of oval patent foramen are bidirectional, predominantly right side. Heart failure FE: 38% (fig.3). All elements support Ebstein's anomaly diagnosis.

Genetic examination revealed a small skull (PC:-1.5 DS), FA large 4/4 cm, nor-

motensive, mild facial dysmorphia.

The infant received spironolactone during hospitalization, patient's state remaining stationary under treatment.

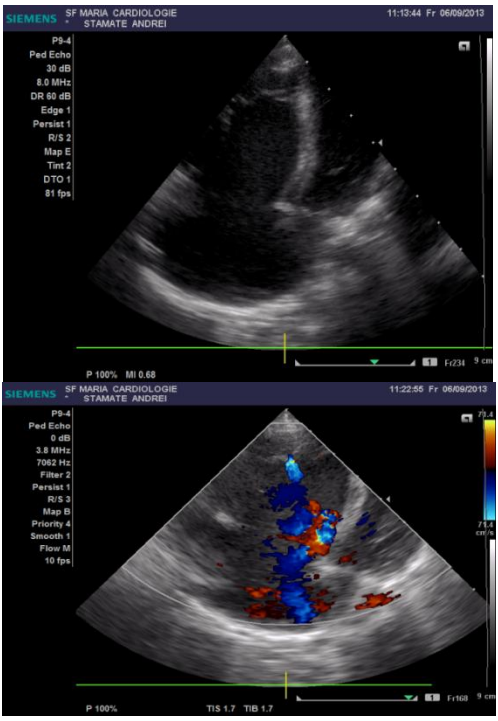

Fig. 3. Patient S.A.G.: echocardiography (four chambers view) Ebstein's anomaly severe form

The patient was transferred to the Institute of Cardiovascular Diseases in Targu Mures for possible univentricular corrections.

Tachycardia with wide QRS (possible antidriomic lead) appeared during hospitalization, with hemodynamic decompensa-tion; after a parenteral load with Amiodarone, electrical cardio version is attempted but the patient relapses in tachycardia, for this reason a beta blocker was added to the initial treatment, being kept short periods of sinus rhythm. The patient is transferred to Department of Pediatric Cardiology, where he continues treatment and held for surgery.

When was readmitted to Pediatric Cardiology Department, patient's state was relatively good, dysmorphic facies, elastic skin, generalized cyanosis, moderate hypotonia, slightly tightened vesicular murmur, intercostal and subcostal circulation. Stetacustic heart - rhythmic heart sounds, noise II duplicated, III noise present, systolic murmur degree III/6 parasternal left. Other signs: abdomen depression, liver 2-3 cm below the costal margin, no signs of meningeal irritation.

Electrocardiogram displayed a sinus rhythm of 120 bpm, axis QRS +60 degree, PQ=0.16 sec, right ventricular overload, major block of right bundle branch, without signs of terminal phase QT: 30 sec.

DISCUSSION

In Ebstein's anomaly, variability of tricuspid valve displacement causes diverse clinical, electrocardiographic, echocardiographic changes. Depending on the anatomical changes, Carpentier made this anatomical and functional classification:

- type A: minimum displacement of the septal tricuspid valve, wide, mobile anterior tricuspid valve, small atralized portion of VD, good functional VD;

- type B: displacement of the septal valve of tricuspid and posterior valve by 25 mm, wide, mobile anterior tricuspid valve, without tracking; relatively good functional VD;

- type C: anterior tricuspid valve partially attached to the VD wall, posterior tricuspid valve agenesis, severe hypoplasia of septal tricuspid valve;

- type D: all right ventricle is covered by anterior tricuspid valve, with minimum systolic opening (4,12).

Heart failure is a major factor in the subsequent management of the case. The

degree of heart failure presented by the infant is supported by the small size of VD, a significant size over 80% of VD atrialization, septal tricuspid valve hypoplasia, left ventricular dysfunction secondary to interventricular septum bulge to the left in diastole, hypoplasia of left heart HTAP (9).

Symptoms were present even at birth with generalized cyanosis, SaO2 (-): 85%, tachypnea and tachycardia; it progressively worsened due to hypoglycemia, neonatal hypothermia and maternal fetal infection.

Although electrocardiography is a classical method which is considered to be the first choice for Ebstein disease severity detection, recent studies support a close relationship between morphological changes of assessed complexes and echocardiographic modifications or nuclear magnetic resonance (10).

Cardiac arrhythmias: Paroxysmal supraventricular tachycardia, ventricular tachyarrhythmias secondary to VD and VS damage are a negative prognostic factor and ablation is indicated using radiofrequency.

In patients with severe tricuspid regurgitation, class III-IV NYHA heart failure, cyanosis, dilation or dysfunction of VD, monocuspe tricuspid valve reconstruction from anterior foil of anterior tricuspid simultaneously with DSA closure are indicated (11, 12, 13).

CONCLUSIONS

Ebstein's anomaly is one of the rarest congenital heart diseases with highly variable evolutionary spectrum.

Newborns having pronounced cyanosis, heart failure phenomena, cardiac arrhythmias, cardiomegaly with increased cardiothoracic index and severe hypoplasia of the septal tricuspid valve lead to a negative outcome in case of Ebstein's disease.

NEWS

A SYSTEMATIC REVIEW AND META-ANALYSIS OF 18F-LABELED AMYLOID IMAGING IN ALZHEIMER'S DISEASE

Timely diagnosis of dementia removes prolonged uncertainty, unnecessary investigations, delays in initiation of symptomatic treatments, and recruitment of poorly characterized patients into research trials. Definitive diagnosis may only be achieved by histopathological examination of invasive brain biopsy or postmortem tissue, or molecular genetic testing in a minority with inherited dementia. Clinical diagnostic criteria in recent use for Alzheimer's disease (AD) often fail to differentiate accurately between AD and non-AD pathology with up to 40% of patients diagnosed with non-AD dementias identified as having pathology consistent with AD at postmortem in some series. When considering the pathophysiology of AD, it has been proposed that the presymptomatic phase is characterized by an early rise in amyloid accumulation, followed later by synaptic dysfunction, tau-mediated neuronal injury, reduction in brain volume, and finally emergence of cognitive symptoms, followed by a clinical syndrome of frank dementia. This suggests a sensitive and specific biomarker of brain amyloid deposition, such as amyloid imaging, would be a useful diagnostic tool, perhaps as an adjunct to investigation of cerebrospinal fluid (CSF) biomarkers (including amyloid and tau), cerebral hypometabolism ascertained by 18Ffluorodeoxyglucose positron emission tomography, hippocampal volume, tractography, and clinical cognitive assessments. The most widely studied radiolabeled amyloid ligand, 11C-labeled Pittsburgh compound B (11C-PiB), demonstrates high affinity and selective amyloid binding. But, disadvantages including expensive technique, a radioactive decay half-life of only 20 minutes and a scanning time of 30 minutes, limited its utility in clinical settings. Nowadays, amyloid imaging using three novel fluorine 18–labeled (18F) tracers, 18F-florbetapir, 18F-florbetaben, and 18F-flutemetamol, with a longer half-life than 11C-PIB of 110 minutes has recently been investigated in a number of studies, including phase 2 clinical trials. These agents have recently gained approval for use in clinical practice. The benefits of identifying amyloid in vivo extend to monitoring disease progression, and, with the advent of treatments targeting amyloid deposition, potentially also as a surrogate biomarker of treatment efficacy. In conclusion, this systematic review and meta-analysis has demonstrated favorable sensitivity and specificity of amyloid imaging with novel fluorine tracers in diagnosis of AD, supporting their use as an adjunct in clinical practice (Yeo JM, Waddell B, Khan Z, et al. A systematic review and meta-analysis of 18F-labeled amyloid imaging in Alzheimer's disease. *Alzheimer's & Dementia: Diagnosis, Assessment & Disease Monitoring* 2015; 1: 5–13).

DIABETES MELLITUS, CHRONIC COMPLICATION IN PATIENTS WITH ACROMEGALY: CASE REPORT AND REVIEW OF THE LITERATURE (Abstract)**:** Disturbances of glucose metabolism are frequently observed in patients with acromegaly. Excess amounts of GH and IGF1 interacts with metabolic regulation, and indeed, GH hypersecretion is associated with hepatic and peripheral insulin resistance; this and also other mechanisms are involved in the development of diabetes mellitus. It can quickly improve if the levels of GH decline after the therapy. **Case report**: We present a patient of 54 years old, admitted in the clinic in 2009, with diagnosis of acromegaly. MRI scan reveals an expansive pituitary tumor 15/16/17 mm. Values of GH, IGF1 and blood glucose were much above normal. Body mass index 27, 5 kg/m^2. After 12 months of a medical treatment with somatostatin analogues, the evolution of blood parameters was favorable, but the patient has discontinued his treatment. At the hospitalization in 2012 there is a precarious control of the diabetes under oral antidiabetic agents. A new treatment has been applied: it was practiced surgical transsphenoidal ablation. At last admit, May 2014, the value IGF1 has been normal, GH has been below 1 ng/mL, and HbA1c was 5.27%. Dyslipidemic syndrome has been constantly present; the values of triglycerides and cholesterol should be a little more upper limit. **Conclusions:** Following successful treatment of acromegaly with surgery, glucose tolerance improves. Balancing type 2 diabetes, with return to normal HbA1c and the decrease in cholesterol and triglycerides values, represents the result of favorable normalization GH in our patients with acromegaly. **Keywords:** DIABETES, ACROMEGALY, TRANSSPHENOIDAL SURGERY.

Acromegaly is a condition characterized by oversecretion of growth hormone (GH) and insulin-like growth factor 1 (IGF1). In 98% of cases hypersecretion due, to a pituitary somatotrophic adenoma; in the other cases (less than 2%) it is the result of over-secretion of Growth Hormone Releasing Hormone (GHRH) from a hypothalamic lesion or from a carcinoid tumor of the gut or pancreas(1). Occasionally acromegaly is found in association with glands, pancreatic islet cells, tumors like glucagonoma, insulinoma and gastrinoma, cutaneous tumors that include multiple angiofibromas, as part of Multiple Endocrine Neoplasia syndrome (MEN) Type 1 (2).

Disturbances of glucose metabolism are frequently observed in patients with acromegaly. The correlation between acromegaly and diabetes was noted as early as 1884 by Loeb (3). Some studies have shown that the incidence of hyperglycemia and glycosuria in acromegalic patients may vary between 10-40 % (4, 5, 6) or over 60% of patients with acromegaly include diabetes mellitus, impaired glucose tolerance and impaired fasting glucose (7, 8). French Acromegaly Registry reported a 22.3% incidence of diabetes mellitus (DM) in acromegalic patients (9). The diagnosis of acromegaly is usually delayed for years, exposing patients to slowly evolving chronic complications (8), that may include: high blood pressure (hypertension) cardiovascular disease, particularly enlargement of the heart (cardiomyopathy), osteoarthritis, diabetes mellitus, precancerous growths (polyps) on the lining of colon, sleep apnea, carpal tunnel syndrome, reduced secretion of other pituitary hormones (hypopituitarism), uterine fibroids, benign tumors in the uterus, spinal cord compression, vision loss. The development of carbohydrate metabolism disorders and/or progression to diabetes in patients with acromegaly may depend on several factors, such as age and gender (10), the levels of GH (11), as well as the duration of acromegaly and duration of exposure to elevated GH levels (9,11). A further possible factor involved in the early development of diabetes is a positive family history of DM (10, 12). A final factor that may also influence the development of glucose disturbances is the specific treatment for acromegaly. Somatostatin analogues may influence glucose metabolism both by lowering insulin secretion and by lowering GH and IGF1 levels (13, 14). The average interval between the onset of acromegaly and that of DM was 9.5 years; however, simultaneous onset of acromegaly and diabetes mellitus was noted in as many as 46.8% patients (9).

CASE REPORT

We present a patient of 54 years old, admitted in the clinic in 2009, with diagnosis of acromegaly. MRI scan reveals an expansive pituitary tumor 15/16/17 mm. Value of GH has been 74ng/mL, (N: 0-3), IGF1 has been 477 ng/mL (N: 93-410) and blood glucose was 168mg/dL. Body mass index (BMI) was 27.5 kg/m². A medical treatment with somatostatin analogues was initiated.

After 12 months of Sandostatin LAR- 20 mg/28 days, the evolution of blood parameters was favorable, but the patient has discontinued his treatment. At the hospitalization in 2012 there is a precarious control of the diabetes under oral antidiabetic agents: blood glucose was 325 mg/dL, HbA1c value was 9 % and the GH increased at 104ng/mL. A new treatment with the intention of the decrease in the GH has been applied: it was practiced surgical transsphenoidal ablation. The cyto-pathological interpretation: pituitary adenomas with somatotoph cells. Evolution after surgery was favorable. At last admit, May 2014, the value IGF1 has been normal, GH has been below 1 ng/mL, and HbA1c was 5.27 %. Joint dyslipidemic syndrome has been constantly present; the values of triglycerides and cholesterol should be a little more upper limit. BMI = 27 kg/m².

DISCUSSION

Disturbances of glucose metabolism in acromegaly can be explained by the direct hyperglycemic effects of GH excess. Excess amounts of GH and IGF1 interacts with

metabolic regulation, GH hyper-secretion is associated with hepatic and peripheral insulin resistance (15). Insulin resistance is also worsened by the lipolytic action of GH generating non-esterified fatty acids that act on the liver to increase hepatic glucose production and inhibit muscle utilization of glucose. Nabarro et al. (11) have reported the results of a large cohort of 208 patients among which 48 had diabetes. They found a significant correlation between age, duration of evolution of acromegaly, and GH level with the presence of diabetes but only by univariate analysis because of the insufficient size of the cohort. Biering et al. (16) have identified age but not GH level as risk factor for diabetes. Møller et al. (17) have studied insulinresistance in acromegalic patients before and after adenomectomy. They have demonstrated that insulin resistance in acromegalic patients is relieved after adenomectomy. The precise mechanism of insulin resistance in the presence of excessive chronic GH is still not clear. GH has a short-term insulin-like effect, but chronic exposure impairs insulin response. Cross talk between GH receptors and insulin receptors have been demonstrated. Hyperinsulinism, insulin resistance, and diabetes are well-recognized cardiovascular risk factors in general population and may contribute to the increased cardiac morbidity and mortality of acromegalic patients (18-21). Clinically, therefore, diabetes in acromegaly resembles Type 2 Diabetes. Diabetic complications, such as retinopathy, are rare but can be seen occasionally. Diabetic ketoacidosis is rare. Age at diagnosis of acromegaly, body mass index, hypertension and duration of evolution of acromegaly were significant independent risk factors associated with development of diabetes. For an acromegalic patient, the risk for the presence of diabetes was increased by 4.4% by age and 12.9% by additional BMI (kg/m^2). Presence of hypertension increased the risk of diabetes by 2.5%. Prevalence of diabetes compared the studies, may be very different: The Spanish (22) and the Belgian registries (23) found a still higher incidence of 37.6 and 25.3% respectively. In the French Acromegaly Registry (9), the prevalence of diabetes was 22.3%. In a study published previously which observed the prevalence of DM in 213 patients with acromegaly, we found 24 cases of DM which represent 11.2 % (5). Diabetes was diagnosed at the same time as acromegaly in 46.8% of patients (9). For other patients, the discovery of diabetes predated the diagnosis of acromegaly with a mean duration of 5.8 years (9) or mean duration of active acromegaly before diagnosis 7.5 years as well as discrete female predominance (5, 12, 13). Although based on the clinical estimation and patient anamnesis, diabetes was present before the presumed beginning of acromegaly in 9.8% of patients (9) or in 20.8% (5). Complications are frequent and the consequences of a delayed diagnosis 5% of patients presented with arterial hypertension (5, 9) rheumatologically complications or pituitary deficiencies.

Diabetes was treated with diet, metformin alone, sulfonylureas associated with metformin, and insulin in 17.6-30% of patients (5, 9). Furthermore, after treatment of acromegaly, diabetes disappeared in 30% of the cases and treatment could be reduced in a number of other cases. Another question is the impact of different treatments of acromegaly in the evolution of diabetes. Ronchi et al. (24) have compared two somatostatin analogs (octreotide LAR versus lanreotide SR) describing a decrease in insulin resistance with both drugs, oc-

treotide LAR appearing more detrimental to diabetes than lanreotide. In a study by Colao et al. (25), where a group of patients was treated for 5 years with somatostatin analogs, no significant change was noted on the prevalence of diabetes during the study duration, although HOMA-R and HOMA-b significantly decreased. Møller et al. (17) have showed a complete reversal of insulin resistance and glucose and lipid metabolism in acromegalic patients cured by adenomectomy. In a study by Kinoshita et al. (26), glucose metabolism in patients cured by surgery was improved when patients had preserved b-cell function.

CONCLUSIONS

In our patients with acromegaly, balancing type 2 diabetes, with return to normal HbA1c and the decrease in cholesterol and triglycerides values, represents the result to favorable normalization of GH.

SINGLE INCISION TRANS-UMBILICAL TOTAL HYSTERECTOMY: ROBOTIC OR LAPAROSCOPIC?

The aim of this study was to compare the early surgical outcomes in patients who underwent total hysterectomy with laparoendoscopic single-site surgery (LESS-TH) versusn robotic single-site total hysterectomy (RSS-TH). Methods: Twenty-four patients who underwent RSS-TH and thirty-four patients who underwent LESS-TH were retrospectively evaluated. Patient characteristics, operation time, intraoperative data (conversions, complications, estimated blood loss, etc.) and postoperative pain scores were compared. Results: The total operation time was significantly longer in the robotic surgery group, with a time of 98.5 vs. 86 min ($p = 0.013$), while vaginal closure time was significantly higher in the laparoscopic surgerygroup ($p = 0.011$). Intraoperative outcomes and postoperative pain scores were similar in the two groups. Conclusion: RSS-TH helps surgeons to overcome the technical disadvantages of LESS-TH, particularly vaginal cuff closure, ergonomics and instrument crowding and clashing. Early surgical outcomes are comparable in the two groups, and both techniques are safe and feasible. (Akdemir A, Yildirim N, Zeybek B, Karaman S, Sendag F. Single Incision Trans-Umbilical Total Hysterectomy: Robotic or Laparoscopic? *Gynecol Obstet Invest* 2015 Jan 27. Epub ahead of print)

ABDOMINAL RADICAL TRACHELECTOMY AS A METHOD OF PRESERVING FERTILITY IN PATIENTS WITH CERVICAL CANCER (Abstract): Cervical cancer is the 4th most common type of cancer in women across EU. However, in women of reproductive age, the incidence of this pathology is high, therefore, over the last decades various strategies have been developed with the purpose of preserving fertility in oncological patients. This paper aimed at reviewing the existing literature information regarding the use of abdominal radical trachelectomy as a method of fertility sparing treatment for patients with early invasive cervical cancer injuries, without neglecting to emphasize on the surgical, obstetrical and oncological outcomes of this procedure. **Keywords:** CERVICAL CANCER, FERTILITY PRESERVING, ABDOMINAL RADICAL TRACHELECTOMY.

Apart from breast cancer, which is the most frequently encountered cancer in women, cervical cancer is the second most common malignancy in women, over 12,000 cases of invasive cervical cancer being annually diagnosed. Although the average patient age at diagnosis is around 50 years old, younger women are also being at risk of developing it, around 20% of the patients diagnosed being under their '40.

Over the past decade, several screening programs have been developed for the most frequent types of cancers in women, aiming at systematically applying a routine test in the asymptomatic population to identify people with pre-cancerous, incipient lesions, perfectly curable by appropriate treatment.

The European Union Public Health provided financial support for the development of screening programmes for cancer thereby, in many EU countries, there is a trend in the implementation of screening programs for reproductive age women, thereby, many oncological patients may be diagnosed with cervical cancer in the early-stage (FIGO IA1-IB1), an essential condition if fertility preservation is desired. In contrast to the global rate, in the EU, the incidence of cervical cancer is low due to the effective implementation of cervical cancer screening programs. The incidence

of cervical cancer is comparatively low in the EU due to the effective implementation of cervical cancer screening.

Unfortunately, the incidence of cervical cancer in our country, as well as mortality from this cause, places Romania at the top of the Eastern Europe region and European Union ranking despite the screening programs that have been implemented through the national health system in our country (1).

The treatment for cervical cancer has evolved considerably in the recent years and is now focused on preserving fertility of the oncological patients of reproductive age. Dissimilar to standard cancer treatment which may include surgery, chemotherapy, radiotherapy or a combination thereof, and aims solely at treating the condition, the radical trachelectomy represents a new surgical approach that emphasis on treating the malignant disease and retain fertility in patients wanting to conceive (2).

This paper aimed at reviewing the existing literature information regarding the use of abdominal radical trachelectomy as a method of fertility sparing treatment for patients with early invasive cervical cancer injuries, without neglecting to emphasize on the surgical, obstetrical and oncological outcomes of this procedure.

Selection of eligible patients using determinant criteria

To achieve the best oncologic results while ensuring the preservation of fertility is essential to consider a series of determinant criteria that will enable the medical team to select the eligible patient that might benefit from this surgery. The eligibility criteria for patients that undergo this procedure were firstly proposed by Roy and Plante (1998) and included aspects regarding the size of the lesion, which should be 2 cm or even smaller, diagnosed as FIGO Stage IA1, without any vascular invasion, FIGO stage 1A2 or 1B1(3). Additionally, the authors recommended at least 5 mm clear margin after the resection and proposed that any possible involvement of the upper endocervical canal, as well as any lymph node metastasis should be excluded by magnetic resonance imaging (MRI).

The outcome of this procedure depends crucially on the selection of the patients, thereby there are specific contraindications. For example, in the case of neuroendocrine and small cell tumors, this procedure may not be considered an option due to the poor prognosis and the high risk of distant metastasis, which are frequently observed in these cases (4, 5). The dimensions of the tumors, the amount of unaffected cervical stroma, as well as the possible involvement of the parametrium may be determined using ultrasonography or magnetic resonance imaging (MRI). Generally, tumors larger than 2 cm are accompanied by invasion of the vascular space, extension of the lesions towards the upper endocervix or parametrium.

Unlike magnetic resonance imaging (MRI) or computed tomography (CT), which have proven ineffective in detecting any possible lymph node metastases, sentinel lymph node mapping (SLNM) performed during pelvic lymphadenectomy appears to be the most precise way for assessing the status of the pelvic lymph nodes.

The approach depends on the tumor type, for example in the case of type IA1 tumors, without lymphovascular space invasion, a cone biopsy may be taken into consideration, whereas in the case of type IA1 tumors with lymphovascular space invasion, it is necessary to combine the cone biopsy with lymphadenectomy. On

the other hand, IB1 tumors larger than 2 cm and IB2 tumors may be highly challenging due to the risk of lymph node involvement, therefore in these cases the fertility preservation may not be an option.

Types of radical trachelectomy techniques

Radical trachelectomy, which may be approached vaginally or abdominally represents a conservative procedure that implies the resection of the cervix, parametria (tissue adjacent to the cervix), and paracolpos while the uterine corpus and fundus are preserved, thereby ensuring the ability to carry a pregnancy (6).

Vaginal radical trachelectomy (VRT), was first developed in the late '80, for the treatment of stages IA2 to IIA type of cancers, and involves the removal of the cervix, a part of the parametrium, as well as the one third of the upper part of the vagina, while preserving the uterine fundus. The procedure may be associated with pelvic lymphadenectomy. One disadvantages of this method is a higher recurrence rate, possible due the incomplete removal of the parametrium, where metastases are often confirmed by histopathological exam, as highlighted in 1996 by Benediti-Panici (7).

Abdominal radical trachelectomy (ART) is a procedure firstly described by Romania gynecologist Eugen Aburel in the early '30, but in 1997, Smith was the one who proposed this approach as a fertility-preserving method in oncological patients (8). In contrast to vaginal radical trachelectomy, the abdominal approach resembles more the traditional hysterectomy, thereby being more easily implemented in hospitals since it does not require advanced laparoscopic skills with are essential for performing VRT. Besides, due to its radical approach, the complete removal of the parametrium is more achievable.

Moreover, ART with pelvic lymphadenectomy is an alternative procedure in cases with distorted cervicovaginal anatomy in which the vaginal approach may not be feasible, or in patients who have severe cervical and upper vaginal scarring, such as those with repeated conization of the cervix.

Abdominal radical trachelectomy – surgical technique steps

The first step consists in opening the abdomen using a vertical incision on the midline. The external and internal iliac fossae lymph nodes and as well as the obturator one is removed and subsequently, frozen sections are prepared for histological examination. Like radical hysterectomy, the ureters are dissected, and the ureteric tunnels are the opened (9). The uterosacral ligaments and the parametrium must be divided. The next step consists in opening the vagina, retrace the uterus, cervix and parametrium superiorly and subsequently amputate the cervix, parametrium and vagina. Histopathological examination by frozen section is used to analyze the superior margins of the amputated cervix, as well as the margins of the still existing cervical tissue to ensure that the margins are tumor-free. These investigations are conducted to establish that after the reconstruction, there are no cancerous cells at the level of the uterus and vagina (10). If a proper margin is available after the amputation, then the surgeon may perform cerclage suture which will be inserted at the level of the cervical stump thereby ensuring future cervical competence. Further on, the occlusion of the surgical-formed cervical canal may be prevented by inserting

and fixing a catheter in the external region of the uterus. Finally, the vagina is sutures and the abdomen is closed.

The general complication rate for this intervention has been reported to be like that of radical abdominal hysterectomy. Specific complications for radical trachelectomy include cervical stenosis, amenorrhea, cerclage expulsion, an increased risk of spontaneous abortion and premature delivery (11) and Chorioamnionitis caused by disruption of the endocervical glands and reduced secretion of mucus (12). In the case of a pregnancy, patients that undergo such a procedure must deliver via classical Caesarean section. There is a minimal risk of secondary infertility since the mucous secretions are indispensable for the endocervical ascension and maturation of sperm. Additionally, the occurrence of adhesions following surgical intervention is not excluded.

The emergence of a new branch of oncology named oncofertility and oncogenetics led to the development of new approaches for pregnancy and birth monitoring consecutive radical trachelectomy with or without iliac lymphadenectomy, a procedure which is performed as a treatment for cervical cancer. In this particular situation, a uterine tranche is sutured directly to the vaginal stump and it has been demonstrated that if a pregnancy occurs, the gestational sac may be restrained through the contraction of the segmental uterine muscle at the level of the isthmus, even in the absence of the cervix.

Surgical and obstetrical outcomes after abdominal radical trachelectomy

The abdominal radical trachelectomy has the advantage of enabling the excision of even larger cervical tumors (up to 4 cm) stage IB1 or IB2. However, according to studies conducted by Wethington, the obstetric outcome after abdominal trachelectomy is less favorable (13). Furthermore, in one of the studies, conducted in two hospitals from Romania, the authors reported that 7 women from a total number of 23 patients that underwent the surgery, attempted to conceive, only 3 of them succeeding. Eventually, only one of the pregnancy was finalized with the birth of a healthy baby at term, while the other two were miscarriages (14).

Accordingly, a study regarding the reproductive and obstetrical outcomes of 114 patients who underwent a radical abdominal trachelectomy previous their pregnancy was retrospectively analyzed. The pregnancy rate in this case was 36.2%, nevertheless, 64.7% of the patients gave birth prematurely. In addition, a study conducted by Okugawa on 151 patients, revealed that pregnancy rate among the patients that tried to conceive after abdominal radical trachelectomy was 25%, 15 women from a total of 61, achieving pregnancies, which were delivered by C-section (15). It is worth mentioning that premature rupture of the uterine membranes occurred in 6 of cases.

Martínez-Chapa highlighted the crucial role that cerclage plays in delivering the baby at term (16). In fact, increasing the rate of full-term birth is one of the ultimate goals of specialists as reported by Tamauchi, since presently, only one third of the pregnancies are delivered at term (17). A study led by Okugawa, also emphasized on the necessity of preventing possible complications that may arise during pregnancy and often result in rupture of the membranes and premature delivery (18).

The patients must wait at least six months following radical trachelectomy

before attempting to conceive. Because of trachelectomy, the cervix or lower uterus becomes scarred and beside cervical stenosis, difficulties in becoming pregnant naturally may occur. This inconvenient may be over fulfilled through assisted reproductive techniques, such as intrauterine insemination, in vitro fertilization, or even embryo or oocyte cryopreservation before surgery. Given the increased risk of second trimester pregnancy loss and preterm birth, an eventual pregnancy must be followed closely, and serial ultrasound examinations will be performed to monitor cervical length (19).

In the event of a preterm delivery, the cervix opens or thins earlier than normal. In this case, antenatal glucocorticoids will be administered to ensure to fetal lung maturation (20). Vaginal delivery should be avoided because a lateral cervical tear in the short-scarred cervix may extend into the nearby uterine vessels, resulting in catastrophic hemorrhage.

When it comes to oncological outcome, a study conducted by Pareja highlighted that only 3.8% of patients presented cancer recurrence, from a total of 485 patients that underwent a procedure of abdominal radical trachelectomy (21). In 9.5% of the cases, several postoperative complications were identified, the most common being cervical stenosis. Notwithstanding, over 85% of the patients managed to preserve their fertility and 67 patients from a total of 113 who tried to conceive, manage to obtain a pregnancy (59.3%).

Nevertheless, monitoring a pregnancy after abdominal radical trachelectomy requires special attention and should involve a multidisciplinary team composed of obstetrician, surgeon, neonatologist and oncologist.

CONCLUSIONS

We may conclude that abdominal radical trachelectomy represents a fertility-sparing procedure for patients diagnosed with early invasive cervical cancer that intend to conceive.

The pregnancy rates have improved significantly over the last years, however, only one third of the pregnancy are delivered at full-term, which is why the medical management is extremely complex.

CELIAC DISEASE: 10- YEAR EXPERIENCE IN A ROMANIAN TERTIARY CENTER (Abstract) A**im:** To evaluate the experience of a single coeliac center over a 10-year-observational period. **Material and methods:** Between January 2003 and December 2013 a total of 195 consecutive patients admitted with celiac disease were tested by multiple duodenal biopsies, anti-tissue transglutaminase and anti-gliadin antibodies, and baseline demographic, clinical, biological and immunological parameters. **Results:** Patients were divided into two major groups according to the clinical features and number of signs and symptoms present upon admission: gastrointestinal (131, 67.17%) and non-gastrointestinal (64, 32.8%). Anti-tissue transglutaminase and anti-gliadin antibodies showed seropositivity in 109/158. Histological samples were available in 152 cases, according to Marsh-Oberhuber classification 11.18% being type 0, 17.76%, type I–II, and 71.05% type III. Correlations between anti-tissue transglutaminase antibody titers and Marsh-Oberhuber classification were found to be statistically significant. Body mass index was available in 96 cases. We found that severe atrophy was predominant in patients with a BMI<18 kg/m^2. **Conclusions:** Celiac disease has an increasing prevalence and can be diagnosed at any age. Histology samples were indicative of different stages of villous atrophy. The disease prevalence is significantly higher among women. There was no statistically significant correlation between Marsh classification and BMI values. **Keywords:** CELIAC DISEASE, ANTI-TISSUE TRASGLUTAMINASE ANTIBODIES, ANTI-GLIADIN ANTIBODIES, MARSH–OBERHUBER CLASSIFICATION.

Celiac disease (CD) is a chronic multi-systemic immune-mediated entero-pathy precipitated by exposure to dietary gluten in genetically predisposed individuals (1).

Until the 1970's, the estimated global prevalence of celiac disease in the general population was just 0.03% (2). The risk for the development of celiac disease appears to increase as one lives longer. Celiac disease is being increasingly recognized in the elderly (3); 2.5 % of the elderly in Finland have celiac disease compared to 1 % in children (4, 5). It is unlikely that genes have changed, and there is evidence that gluten exposure has not either (6). In clinical and pathological terms, our understanding of the disease has considerably improved in recent decades, thus making an accurate diagnosis possible. Despite the huge interest for CD for both the general population, gastroenterologists and general practitioners according to current

knowledge there is still a lack of celiac patients cohort trials. In the past 5 years the size of CD patient population in our centre has been growing rapidly with a huge prevalence of CD among atypical nonspecific presentation and first degree relatives. We performed a retrospective review of the medical records of all patients diagnosed with CD and followed up at our hospital in the past 10 years in order to see if the trend is similar to that reported in the literature (7-10).

MATERIAL AND METHODS

The data for this retrospective cohort study were taken from a database of CD patients assessed at a Iasi town tertiary referral center between January 2003 to December 2013. The study is part of a single-center research aiming to investigate the true prevalence of celiac disease. We collected data from 147 female and 48 male patients (75.3% *vs.* 24.7%, respectively), with a mean age of 33 years, range 18 - 68 years. The yearly distribution of patients enrolled in this study is shown in figure 1.

The graph shows an increasing incidence of celiac disease due to increasing awareness and knowledge of pathophysiology, wide spectrum of clinical presentation, disease progression, and pathological mucosal intestinal features, which range from early and mild clinical forms of disease to severe villous atrophy.

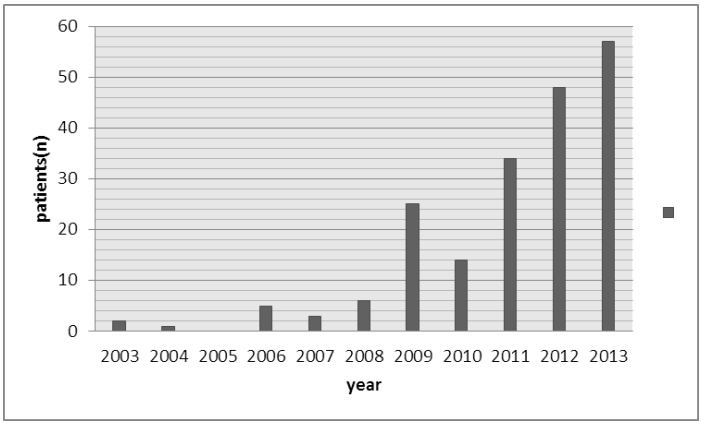

Fig. 1. Celiac disease cases over a ten-year period

Patients with serology (anti-gliadin or anti-transglutaminase) and histology (DII, DIII, bulb) performed within 3 to 6 months of each other were included in the study.

Patients were divided into two major groups categorized by their clinical features according to the number of signs and symptoms present upon admission: gastrointestinal (GI): non- specific abdominal pain, dyspepsia, bloating, flatulence, heartburn, chronic diarrhea, unintentional weight loss; and non-GI: iron deficiency anemia, dermatitis herpetiformis, osteoporosis, elevated liver enzymes, chronic fatigue, joint pain, headache, infertility, ataxia, epilepsy, aphthous stomatitis.

Patient consent was obtained before further examinations including quadrant biopsy specimens taken from the bulb, second or third part of the duodenum. Duodenal histology samples were taken in 152 (77.9%) cases. The mucosal specimens were

graded independently according to Marsh-Oberhuber classification as follows: type 0 - normal villi, type I-II - normal villi but intraepithelial lymphocytosis without (I) or with (II) hyperplastic crypts, type III a-c - varying degrees of villous atrophy with hyperlplastic crypt (1). Immunohistochimical studies were performed and CD3+IELs were counted with a 100 x flat field light microscope objective. The histological evaluation was performed in the Department of Pathology of the hospital.

Serological results were based on measuring tissue transglutaminase antibody (anti-TTG) IgA and IgG (normal range: 0–30 U/ml) and anti-gliadin (anti-gl) antibodies (normal range: 0-12U/ml). The IgG antibody tests were applied for cases of selective IgA-deficiency. Baseline serology data of 158 patients were available.

Positive diagnosis was made using a combination of findings from the medical history, physical examination, serology, and upper endoscopy with histological analysis of multiple biopsies of the duodenum. A positive CD-specific serology in patients with villous atrophy confirmed the diagnosis of celiac disease.

Data were analyzed with the SPSS Software for Windows Version 17.0 (SPSS Inc., Chicago, Illinois). Quantitative data were expressed as the number of subjects and percentages, or as medians and ranges. When appropriate, the Pearson correlation coefficients were used to assess correlations between different variables. A p-value <0.05 was considered statistically significant.

RESULTS

Celiac disease was found in 131 (67.17%) patients in the GI group, 99 (75.57%) females. The most frequent complaint was upper abdominal pain, loose stools accompanied by bloating and abdominal discomfort irrespective of bowel movement. In the non-GI group composed of 64 patients (39: 60.9% females), most of the patients (47: 24.10%) were referred to our clinic for investigations unrelated at first glance to digestive disease: chronic fatigue, joint pain, headache and low iron levels which failed to return to normal after iron supplementation.

Most of the patients had at least one prior admission and at least one other medical prescription. CD was diagnosed in 84 (64.12%) patients in the GI group, and 29 (45.31%) in the non-GI group.

There were 4 patients diagnosed with dermatitis herpetiformis (biopsy-proven) none having any digestive complaint (fig. 2).

Body mass index was available in 96 cases. We found that severe atrophy was predominant in patients with a BMI<18 kg/m^2, and Marsh I, II were common in patients with normal BMI, but there was no statistically significant correlation between Marsh type and BMI values ($p = 0.470$).

The clinical utility of serology testing: Serum IgA class anti-TTG and anti-gl were measured in 145 (74.3%) patients. Values greater than 30U/L (anti-TTG) and 12 U/L (anti-gl) were considered positive. Anti-endomysial (EmA) test results were available in a few cases thus its utility cannot be commented upon.

All patients were screened for IgA deficiency. In case of deficiency the corresponding antibodies were measured in immunoglobulin G (IgG) class.

Nine patients had selective IgA-deficiency; IgG-anti-tissue transglutaminase antibody tests were performed.

Seventy-eight out of 145 patients had anti-TTG, 5 patients had only anti-gl anti-

bodies and 52 patients both anti-gl and anti-TTG. Seropositivity was detected in 109/145 (75%) of cases.

There was a significant association between serum TTG level and clinical presentation, low levels being more common in the screen rather than symptom-detected subjects (fig. 3).

TABLE I

Demographic data on the study participants

Parameter	**Patients**, no=195
Females, %	147 (75.3%)
Age, median (range)	33 (18-68)
Main reason for disease suspicion	
Gastrointestinal symptoms[1],%	131(67.17%)
Iron deficiency anemia/low iron levels%	47(24.10%)
Extra-intestinal symptoms[2],%	64(32.82)
Family history of CD,%	14(7.17%)
IgA deficiency,%	9(6.2%)
Autoimmune disease, %	7(3.5%)
[1] abdominal pain, dyspepsia, bloating, flatulence, heart burn, chronic diarrhea, unintentional weight loss [2] iron deficiency anemia, dermatitis herpetiformis, osteoporosis, elevated liver enzymes, chronic fatigue, joint pain, headache, infertility, ataxia, epilepsy, aphthous stomatitis .	

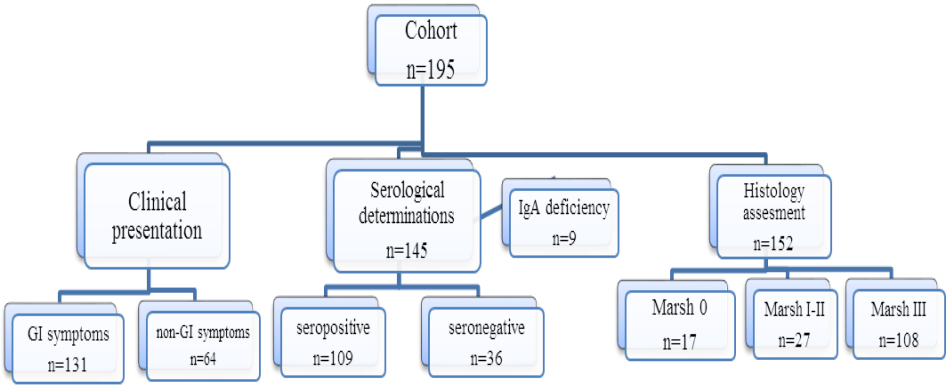

Fig. 2. Flow chart representing the features of celiac disease in our cohort

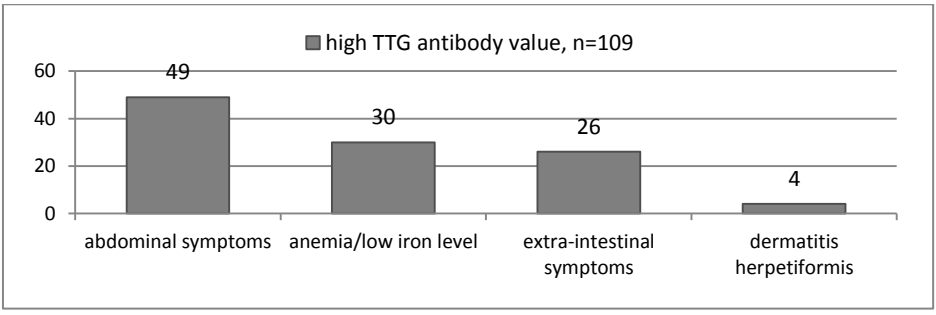

Fig. 3. Serum transglutaminase antibody levels according to clinical presentation

Duodenal mucosal histology Multiple biopsies were taken from the duodenum (DII, DIII) and histological samples were available in 152 (77.9%) patients.

Using the Marsh-Oberhuber classification we found: Marsh 0 in 17 patients, Marsh I-II in 27 patients, Marsh 3a in 35 patients, Marsh 3b in 23 patients, and Marsh 3c in 50 patients. Small bowel mucosal villous atrophy and crypt hyperplasia (Marsh III) were found in 75% of the TG positive subjects. All patients with dermatitis herpetiformis had severe villous atrophy and elevated antibody titers.

Associations between serological testing and mucosal damage: Serological and histological results were available in 132 (67.69%) patients with CD. Ninety-nine (75%) of these patients were serologically and histologically positive for CD. Negative serology and positive histological results were present in 23 patients (17%), and positive serologies with negative histology were found in 10 patients (7%).

Correlation between histological lesions and anti-TG titer was examined in 111 cases. There was a significant association between high levels of antibody and the severity of small bowel mucosal involvement (fig. 4).

	Negative	Marsh I-II	Marsh IIIa	Marsh IIIb	Marsh IIIc
0-30U/ml	5	0	4	2	7
30-50U/ml	1	0	5	0	13
50-200U/ml	1	3	6	8	12
>200u/ml	0	2	16	3	23

Fig. 4. Relation between TG2-ab and the severity of small bowel mucosa involvement

DISCUSSION

In this study we reported data using a multiparametric approach to describe the dynamics of CD over a ten-year period. We analyzed the clinical, serological, histological, and in particular cases the laboratory findings, family history and associated disease of the 195 celiac patients hospitalized in our department between January 2003 and December 2013. Female predominance was obvious in our cohort (75.3% vs. 24.7%), and this prevalence was confirmed by other clinical studies available in literature (2). The mean age of 33 years was indicative of a disease which can be identified in all age groups and not only in children as previously considered.

Serology testing showed a majority of seropositive subjects, but it is important to add that not all the patients met the serology criteria thus stating the need to perform a further duodenal biopsy. In our cohort, 23 patients proved seronegative but with a positive histology. Relying solely on antibody titers to make a positive diagnosis would leave a significant percentage of

patients deprived by a correct diagnosis. Elderly celiac patients were seronegative more often than younger celiac patients. One reason for the low antibody titers in older patients might be the sequestration of antibodies to the intestinal mucosa over time (4).

The vast majority of patients (75%) proved to have severe histological alterations (Marsh III) and the severity of mucosal damage correlated well with antibodies levels. Previous studies have suggested the presence of such correlation by showing parallel alleviation of histologic damage and serology findings (7).

Whilst current literature suggests a discriminatory role for high risk group, our data suggests that there is no single clinical feature of itself a reliable risk stratifies (8). The study had some limitations inevitably, consisting in the uncontrolled, retrospective designed, and in the fact that in some cases, the crucial histological parameters often lacked making the exact definition of CD by Marsh-Oberhuber classification impossible. A major strength in this study is the large number of patients representative of those in everyday clinical practice.

CONCLUSIONS

In our study, we found that celiac disease can be diagnosed at any age. The percentage of females was significantly higher. Histology diagnosis usually showed different stages of villous atrophy. Active screening for CD and its complications and associated diseases is increasing used. Celiac disease must be considered in the differential diagnosis of all patients with malabsorbtion symptoms despite older age in order to prevent disease complications.

MULTIDISCIPLINARY TREATED THYMOMAS WITH FATAL OUTCOME. A RETROSPECTIVE STUDY (Abstract): The **aim** of the study was to assess factors concurring to fatal outcome of patients operated for thymoma with or without myasthenia gravis. **Material and methods:** A retrospective observational study was carried out on a series of 10 patients treated for thymoma in the IIIrd Surgical Unit of "St. Spiridon" University Hospital. **Results:** Mean survival time was 4.45 years and mortality rate was 38,4%. In 8 patients III and IV Osserman stage myasthenia gravis was associated. 2 patients without myasthenia gravis were diagnosed with a locally advanced stage of thymic carcinoma. According to WHO pathological classification of thymoma, 2 cases were included in type C, those without myasthenia gravis associated and the rest in type B1 (2 cases) and B2 (6 cases). According to Masaoka classification all cases presented invasive thymoma: 6 cases type II, 3 cases type III and one case with type IV. Apart of one case in stage IV, all cases benefitted of complete surgical resection. No perioperative and early postoperative mortality was recorded. On long term follow-up the cause of death was related to aggravation of myasthenia gravis in 6 cases, to cardiac failure in 2 cases (acute myocardial infarction and constrictive pericarditis) and in 2 cases to metastatic disease (thymoma related death - 20%).**Conclusions:** Aggravation of myasthenia gravis was the first cause of death in this series in spite of complete resection and intensive immunosupressive treatment. Completeness of surgical resection is the most important prognostic factor. The histopathological type of thymoma with fatal outcome was type B and C after WHO classification. Key words: THYMOMA, MYASTHENIA GRAVIS, FATAL OUTCOME

Thymoma patients are a real challenge for the therapeutic team as the outcome can be unpredictable and the response to treatment sometimes refractory. Although most of the authors consider the association of thymoma with myasthenia gravis a good prognostic factor, because it speeds the disclosure of the thymoma in a resectable stage, we noticed that following an initial improvement, myasthenia gravis might become more aggressive and refractory to immunosuppressive treatment. Another important favorable prognostic factor is the completeness of surgical resection but the influence of pathological type of thymoma remains unclear. The aim of the study was

to assess factors concurring to fatal outcome of patients operated for thymoma with or without myasthenia gravis.

MATERIAL AND METHODS

A retrospective observational study was carried out on a series of 10 patients treated for thymoma in the IIIrd Surgical Unit of "St. Spiridon" University Hospital. From 1990 to 2010, 81 cases of thymic lesions were treated by a multidisciplinary team including neurologist, radiologist, immunopathologist, oncologist, surgeon and anesthetist. Thymoma patients represented 26 cases (32%) and among these patients we selected those who died postoperatively over a period of 16 years.

Demographical data, clinical staging data, tumor extension after Masaoka classification, thymoma type after WHO classification, completeness of surgery, adjuvant treatment and patient follow-up data were obtained from the patients records and from detailed patient or family interviews (tab.I). The end point was mortality of the patients till august 2013.

TABLE I

Clinical and pathological characteristics of the patients.

No. / NAME	SEX	AGE	OSSERMAN	WHO	MASAOKA	OP	MTS	POT	ST	DEATH CAUSE

8.GM	F	31	-	C	III	CR	bone	C/ST	2y	MTS
9.PA	M	41	IIB	B1	II	CR		C	3m	ARF
10.IV	M	54	IIB	B1	II	CR		-	2y	ARF

RESULTS

Survival time ranged between 3 months and 16 years. Mean survival time was 4.45 years and mortality rate was 38.4%.

Sex ratio F/M was 3/2 and mean age at the time of operation was 42.2 years. In 8 patients III and IV Osserman stage myasthenia gravis was associated. 2 patients without myasthenia gravis were diagnosed with a locally advanced stage of thymic carcinoma; in one case resection was feasible while in the youngest one only a biopsy could be performed.

According to WHO pathological classification of thymoma, 2 cases were included in type C, those without myasthenia gravis associated and the rest in type B1 (2 cases) and B2 (6 cases).

According to Masaoka classification which assesses the grade of tumor invasion, all cases presented invasive thymoma which is considered malignant, even in the

absence of cells atypia; 6 cases type II, 3 cases type III and one case with type IV. Apart of one case in stage IV, all cases benefitted of complete surgical resection.

One case presented at 10 years with tumor recurrence that required re-resection with survival time of 6 years, the cause of death being not related to operation or recurrence.

The majority of patients (9 cases) received postoperative adjuvant therapy such as radiotherapy, chemotherapy or both. Radiotherapy was indicated mainly for Masaoka stage III and IV patients.

No perioperative and early postoperative mortality was recorded. At the time of hospital discharge an obvious improvement of symptoms was observed for the patients with thymoma associated with myasthenia gravis.

On long term follow-up the cause of death was related to aggravation of myasthenia gravis (60%) in 6 cases, to cardiac failure in 2 cases (acute myocardial infarction and constrictive pericarditis) and in 2 cases to metastatic disease (thymoma related death - 20%).

DISCUSSION

Thymomas are rare thymic epithelial tumors but represent the most frequent tumor of the mediastinum after the age of 40 without gender preference, unlike lymphoid thymic hyperplasia frequently encountered in young female patients (1, 3).

The presence of myasthenia gravis must be regarded as a favorable factor from the diagnostic point of view because the myasthenia symptoms alert patients to seek medical advice and thymoma in such cases can be discovered in a resectable surgical stage. But in our series the association of severe clinical form of myasthenia gravis seems to be related with fatal outcome. Even after a period of improvement postoperatively, myasthenia gravis has reappeared in aggravated and treatment refractory forms being responsible for acute respiratory failure and death. Aggravation of MG postoperatively might be explained by tumor recurrence or exacerbation of extrathymic autoimmunity.

On the contrary, other studies reported that the presence of myasthenia gravis did not show statistical correlation with survival on a multivariate analysis (1, 2, 4, 9). The reported long-term outcome of thymoma patients is related to tumor stage, WHO histotype, completeness of surgical removal and type of treatment (1, 5, 6).

Morgenthaler et all. found that the prognosis is best predicted by stage of the tumor determined intraoperatively and is poorer in patients with incomplete resection. Irradiation and chemotherapy have important roles in the management of thymomas, particularly in advanced stages (3, 7, 8, 9).

The pathological type encountered in our series after WHO classification was mostly B2 and C, which are recognized as aggressive tumors.

Complete surgical resection is a good prognostic factor and when extended thymectomy is feasible the recurrence of tumor is rare. In one case, recurrence was diagnosed and reoperated at 10 years resulting in a good outcome. The patient survived 6 years after reoperation, the cause of death (acute myocardial infarction) being unrelated to thymoma.

Tumor recurrence is rare in complete resected cases. If over a period of 2 years the disease is well controlled then the chance of prolonged survival is increased. The critical period seems to be 2 years postoperatively in which the patient should be closely follow

up, such as every 3 months.

CONCLUSIONS

The association with myasthenia gravis facilitates the diagnosis of thymomas in an early, resectable stage, but our results suggest that despite an initial improvement, myasthenia gravis might become more aggressive and refractory to immunosuppressive treatment. Another important favorable prognostic factor is the completeness of surgical resection although the influence of pathological type of thymoma remains unclear. In our series, the histopathological type of thymoma with fatal outcome was type B and C according to WHO classification. Aggravation of myasthenia gravis was the first cause of death in spite of complete resection and intensive immunosupressive treatment.

THE EFFICACY OF THE PEGINTERFERON TREATMENT IN CHRONIC HEPATITIS HDV AND COMPENSATE LIVER CIRRHOSIS (Abstract). **Aim**: to evaluate the efficiency of the treatment with Peginterferon alfa 2a 180 mcg/week, 48 weeks in patients with chronic hepatitis or compensated liver cirrhosis HDV and predictive factors of response to treatment**.** **Material and methods**: prospective study that enrolled 50 patients with chronic hepatitis or compensated cirrhosis HDV between the 1st of January 2011 – 3st of December 2011. The diagnosis of chronic HDV infection was made based on the presence of detectable anti HDV IgG antibodies and HDV-RNA. Patients were evaluated at baseline by CBC, liver function tests, HBV profile, HDV RNA, and by liver biopsy/Fibrotest for evaluating fibrosis and necroinflamatory activity. At 24 weeks CBC (count blood cells), liver function tests, quantitative HBsAg and at 48 and 72 weeks biochemical tests, HDV RNA, HBV DNA, quantitative HBsAg, were performed. Adverse reactions to the treatment were recorded. **Results**: SVR (sustained virologic response) was recorded in 12 patients (24%) and biochemical response in 28 patients (56%). SVR was correlated with low-grade fibrosis, age, the aminotransferase value and the value of HBsAg at the beginning of the treatment. In week 48 HDV RNA was undetectable in 20 patients (40%). The therapy was well tolerated, except two patients for whom the discontinuation of the treatment was decided for severe exacerbation of cytolysis, respectively hepatic decompensation. **Conclusions**: In a representative group of patients, the treatment with Peginterferon once again proves its efficacy in treating chronic HDV. **Keywords**: DELTA HEPATITIS, CIRRHOSIS, PEGINTERFERON TRATMENT.

HDV chronic hepatitis is the most severe of chronic viral hepatitis, representing an important public health problem. The hepatitis delta virus (HDV) is a defective RNA virus that requires the presence of the HBV for replication and transmission. Of the HBsAg carriers, approximately 5% also have the HDV infection, affecting 15 to 20 million people worldwide. The evolution is rapid from chronic hepatitis to liver cirrhosis (1) and hepatocellular carcinoma (2).

HDV infection is difficult to treat;

pegylated interferon seems to be the only efficient molecule naive as well as in pre-treated patients, with a virologic response of ~ 20-47 % (3). HDV activity depends on HBsAg, not on the HBV replication or the HBV DNA level (4). Measurement of HBsAg levels during the treatment may be more useful than HDV RNA negativity in predicting the virologic response. The main concern is the use of interferon is neutropenia, thrombocytopenia, and severe hepatic cytolysis flare that may have dramatic consequences in patients with a deficient hepatic reserve (5). Studies with nucleoside analogues demonstrated that these molecules have no effect on hepatitis delta.

The aim of our study is to evaluate the effectiveness of the treatment with peginterferon α2a 180 mcg/week, 48 weeks in patients with chronic HDV infection in chronic hepatitis or compensated cirrhosis, and the predictive factors of response to treatment. TGP normalization at 48 and 72 weeks, HDV RNA negativity and the decrease of HBsAg levels were followed.

MATERIAL AND METHODS

We performed a prospective study that enrolled patients with chronic hepatitis or compensated cirrhosis VHD, present in the Gastroenterology and Hepatology IC Fundeni Clinic during January 1 2011-31 December 2011. The inclusion criteria were: age over 18 years, HBsAg and anti-HDV antibodies of over 6 months, HDV RNA detectable viremia, hepatic cytolysis with ALT $\geq$ 2xN, and histological evidence of chronic hepatitis or cirrhosis. Exclusion criteria were pregnancy, lactation, other causes of liver damage, hepatocarcinoma or decompensated cirrhosis, thrombocytopenia, neutropenia <1.000/mm^3, Hb <9 g/dl, severe cardiac, lung, neuro-psychiatric co morbidities.

Liver cirrhosis was diagnosed by PBH/FibroMax (F4) or imaging studies: abdominal ultrasound or computer tomography. They were evaluated at baseline with the CBC, liver function tests, profile HBV (HBsAg quantitative HBeAg, HBeAb, AcHBc, DNA-HBV), HDV RNA. At 24 weeks CBC, liver function tests, quantitative HBsAg were performed, and at 48 and 72 weeks CBC, biochemical tests, HDV RNA, HBV DNA, quantitative HBsAg.

Quantitative HBV DNA was detected by using the Real Time PCR (detection limit of 5 IU/ml), anti-HDV antibodies through the method ETI-AB-DELTA-2 (Diasorin), HDV RNA by Real Time- PCR (limit of detection 500 IU/ml). The flare was defined as an increase of aminotransferase levels of 3 times in comparison with the value from the onset of treatment (6).

Sustained virological response (SVR) was defined as undetectable HDV RNA at 48 and 72 weeks. The biochemical response is represented by the normalization ALT at the end of treatment. Non-responders were defined as still having detectable HDV-RNA viral load at the end of treatment.

The fibrosis and necro-inflammatory activity were evaluated by liver biopsy (METAVIR score) or Fibrotest, performed at baseline and at the end of the treatment. An improved histological aspect was considered to be the regression by at least 1 point in the fibrosis score and 2 points in the necro-inflammatory activity for the two determinations. The adverse reactions to treatment were also recorded.

Statistical analysis: the continuous variables such as age, the aminotransferasis, the viremia, platelet counts were expressed as mean value +/- SD (standard deviation).

Categorical variables such as gender, environment, response to treatment, stage of fibrosis were expressed as a percentage (and no. of Patients). Comparisons were made using Fisher's exact t-test, the Pearson correlation coefficient and Anova method (unidirectional analysis of variant), through which the predictive response factors were calculated. Differences were considered statistically significant at a p value <0.05. All data were processed using *SPSS 13.0* statistical analysis program.

RESULTS

50 patients were included in the study, 39 (78%) patients with chronic hepatitis and 11(22%) patients with liver cirrhosis (tab. I).

TABLE I

Baseline characteristics of patients

Characteristics	Chronic hepatitis (39p)	Cirrhosis (11p)	p
Age at onset (years)	41.72+/-12.61	49.36+/-10.03	0.0710
Sex	20F/19M	3F/8M	0.1430
Environment	6R/33U	0R/11U	0.2050
AST at onset (UI/l)	77.44+/-29.45	99.45+/-35.78	0.0420
ALT at onset (UI/l)	97.23+/-47.43	126.55+/-37.07	0.0650
Bil T at onset (mg/dl)	0.77+/-0.22	0.97+/-0.19	0.0110
Albumin (mg/dl)	4.52+/-0.45	3.79+/-0.68	0.0000
INR	0.98+/-0.167(1-1)	1.1+/-0.21 (1-2)	0.0600
Leukocytes (/mm3)	6471.03+/-1735.4	4940+/-2116.7	0.0170
Hb (g/dl)	13.82+/-1.35	13.33+/-1.21	0.2790
Platelets ($X10^{3/mm3}$)	192.667+/-52.226	103.091+/-13.397	0.0000
HBsAg	3598.87+/-2661.25	5227.27+/-2446.26	0.0750
HBsAg ($X10^{6}$)	2.41+/-14.75	0.021+/-0.067	0.5960
HDV RNA ($X10^{6}$)	12.66+/-34.083	8.19+/-9.92	0.6710
HBeAg (+) / HBeAg (-)	2p/37p	0p/11p	0.6050
HBeAb (+) / HBeAb (-)	34p/5p	10p/1p	0.6040
AcHBc (+) / AcHBc (-)	38p/1p	11p/0p	0.7800

SVR was recorded in 12 patients (24%), 11 patients with chronic hepatitis and 1 patient with liver cirrhosis, and biochemical response in 28 patients (56%): 25 patients with chronic hepatitis and 3 patients with liver cirrhosis. Among patients with SVR, 3 were pretreated with standard IFN, the remaining 9 patients were naive.

Alanine amino transferase (ALT) was normal in 28 patients at week 48, and in 29 patients at week 72 (fig.1).

At end of treatment (EOT) 20 patients had undetectable HDV RNA viremia. Only 12 of them maintain the same status of HDV RNA. For 8 EOT patients the viremia becomes detectable at 72 weeks. 30 patients (60%) were considered non-responders, 23 with chronic hepatitis and 7 patients with liver cirrhosis (fig.2).

The clearance of HBsAg at 48 weeks of treatment was observed in 1 patient. At 72 weeks from the start of treatment the HBsAg was negative in 12 patients (tab. II). Patients who presented the negativation of the HBsAg were compared with those who did not show the negativation, and it

was found that HBsAg negativation is not correlated with young age 44.42+/-13.44 (p=0.749), sex (F/M 7p/5p) (p=0.257), progressive form of liver disease – chronic hepatitis/cirrhosis (11 p/1p) (p=0.184). HBsAg clearance was associated with decreased ALT 30.05+/-7.052 (p=0.002) and low-grade fibrosis (p=0.048).

HBs seroconversion, with the appearance of anti HBs antibodies was recorded in 5 patients at 48 weeks of treatment and in 17 patients at week 72.

The reduction of the HBsAg level may be a prognostic factor of response to treatment, because HDV requires the presence of HBsAg as an envelope (7).

At baseline the HBV DNA viral load was undetectable in 20 patients, knowing that HBV replication is inhibited by the presence of HDV virus that is dominant. Reactivation of HBV under treatment was recorded in 2 patients from those with SVR.

A liver biopsy was performed for 32 patients, and 18 were evaluated by Fibrotest. The same evaluation by liver biopsy or Fibrotest was performed at the end of treatment. Histological improvement was recorded in 26 patients (52%). No patient recorded a deterioration of the histological aspect.

Predictors for the onset of the response (tab. III): the degree of fibrosis (the lower the degree of fibrosis, the higher is the probability of response) p=001, age of patients at the beginning of the treatment p=0.007, ALT and AST at the onset of treatment p=0.017 vs p=0.030, total bilirubin p=0.005, albumin p=0.000, INR p=0.031, HBsAg at start p=0.000.

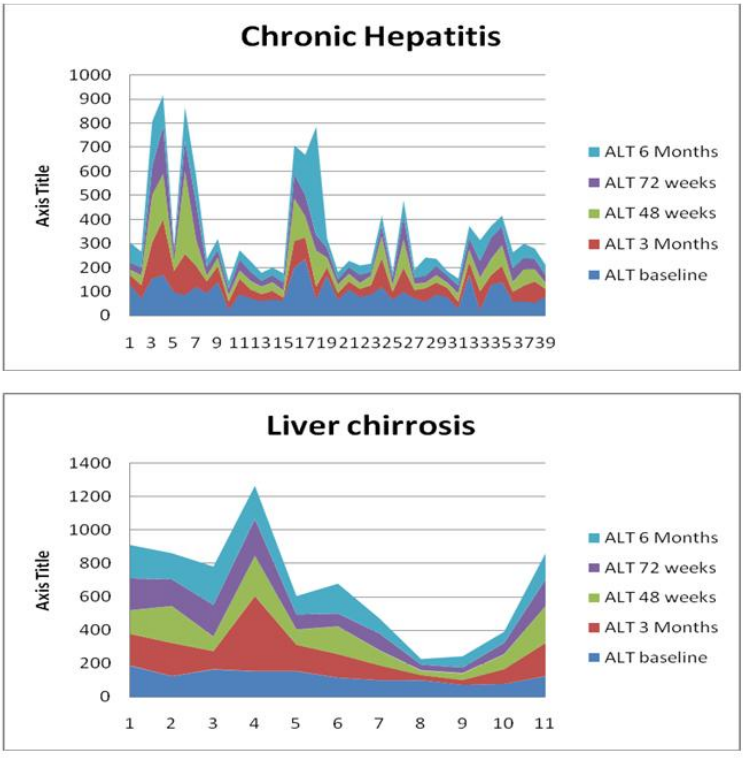

Fig. 1. Evolution of ALT in patients with chronic hepatitis and cirrhosis

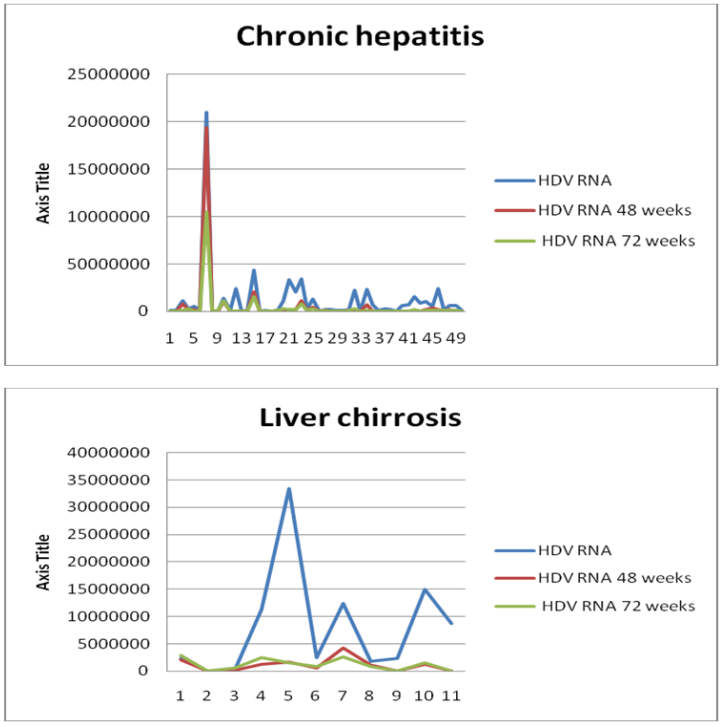

Fig. 2. Evolution of HDV RNA in chronic hepatitis and cirrhosis

TABLE II

Evolution of Ag HBs

	HBsAg at start	**HBsAg at 3 months**	**HBsAg 48 weeks**	**HBsAg 72 weeks**
Mean	3957.12	2251.28	1724.82	1573.16
Std.Deviation	2679.171	2357.786	2072.711	2068.699
Minimum	100	50	0	0
Maximum	9000	8000	7006	7006

The treatment response does not correlate with: sex (p=0.800), HBeAg (p=0.442), baseline viraemia: HBV DNA (p=0.270), HDV RNA (p=0.227).

Although patients with liver cirrhosis were included, tolerability was good (tab. IV).

Thrombocytopenia was more common in patients with cirrhosis: 10% versus 2% in chronic hepatitis (p=0.001); it was not symptomatic and no hemorrhaging manifestations or bleeding was recorded.

Hepatic decompensation occurred in 1 patient (2%): jaundice syndrome (bil T = 3 mg/dl) in week 40 when the treatment was discontinued.

In one of the non-responders, a severe hepatic cytolysis flare was recorded AT x 5 N (2%), the deterioration of the general status caused the discontinuation of treatment at week 26. The only cirrhotic patient who recorded SVR, presented elevated aminotransferases over the entire course of the treatment, but remained asymptomatic.

TABLE III

Evolution of treatment response

Results	Chronic hepatitis	Liver cirrhosis	p
HDV RNA negative at 48 weeks	18p/39p(46.15%)	2p/11p(18.18%)	0.090

Peg IFN dose reductions due to leukopenia was necessary in 3 patients.

Under treatment HBsAg, HDV RNA and HBV DNA have the same trend (fig. 3).

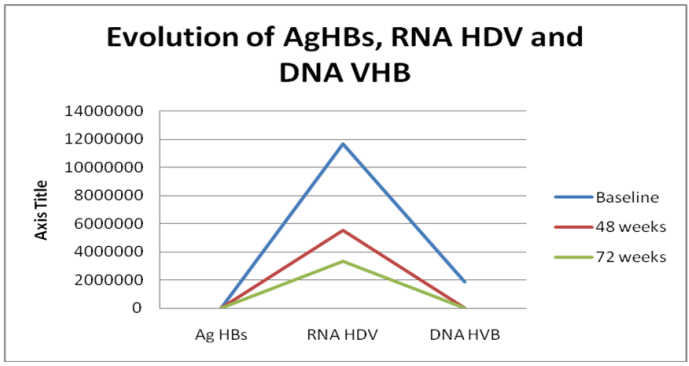

Fig. 3. Evolution of AgHBs, HDV RNA and HBV DNA

DISCUSSION

The Peginterferon treatment resulted in a important reduction of the HDV-RNA at the end of the 48 weeks of treatment, both in patients with hepatitis and with liver cirrhosis, but without statistical significance.

Similar studies have reported values of SVR in chronic HDV infection between 17 and 43%. Niro (37%) (8), Wedemeyer (28%) (9). Erhardt reports a biochemical response in 3 patients (25%) and SVR in 2 patients (17%) (10). Castelnau, in his study conducted on 12 patients, obtains a biochemical response in 8 patients (57%), EOT in 8 patients (57%) and SVR in 6 patients (43%) (11). These results with such different values are probably due to the fact that the studies were conducted on small groups of patients. However, all of them prove the superiority of the Peginterferon treatment versus the standard IFN.

During treatment, ALT levels remain high in many of the patients, especially those with SVR, but there are patients with normal ALT that have not managed to turn their HDV RNA negative. No evidence of a parallel decrease of aminotransferases and HDV RNA was emphasized, so their determination is not of accuracy in the monitoring of the treatment effectiveness.

Although there are studies that show that in the HDV infection as well, HBsAg levels correlate with HDV viremia and can be used as a surrogate marker in monitoring the treatment with PegIFN, in our study we found only the same trend of evolution (12).

In patients with a slow response, which significantly reduce their viremia, but without managing to turn it negative, we wonder if they would benefit from increasing the treatment period beyond 48 weeks. However, there were authors that showed that a 2-year period, is not superior to a 1 year one (13).

As in other studies, the response to treatment was correlated with patient age, low grade fibrosis, the HBsAg and aminotransferases values at the onset of treatment (14, 15). No apparent correlation between the treatment response and HDV viremia was observed, as in other studies (16, 17).

CONCLUSIONS

The treatment with Peg IFNα 2 for a period of 48 weeks is effective. Results, although encouraging, are not maintained over time, at 72 weeks many patients relapse (18).

A CASE OF SEVERE HYPOALBUMINEMIA ASSOCIATED WITH CHRONIC CONGESTIVE HEART FAILURE: THE ROLE OF THE TRICUSPID REGURGITATION (Abstract): Hypoalbuminemia is considered an independent predictor of mortality, especially in elderly patients. It is common in patients with congestive heart failure, when is due to several mechanisms: increased volume of distribution, significant stasis in the mesenteric circulation and altered protein metabolism in the liver. These alterations are even more pregnant when tricuspid regurgitation is associated or aggravated by different risk factors (recent infections, anemia, hyperthyroidism). We present the case of an elderly patient with severe hypoproteinemia and important hypoalbuminemia associated with congestive heart failure and aggravation of tricuspid regurgitation. The differential diagnosis concluded that hypoalbuminemia was influenced by tricuspid regurgitation as it enhanced liver dysfunction and enteral protein absorption due to increased stasis in mesenteric system. On the other hand, hypoalbuminemia contributed to the progression of heart failure by favoring myocardial edema, volume overload, and diuretic resistance. This is why correct management of this situation should include removal of subclinical excess of fluid and renutrition. A multidisciplinary approach is needed in order to achieve a good control of the symptoms and a significant improvement of quality of life. Keywords: HYPOALBUMINEMIA, CONGESTIVE HEART FAILURE, TRICUSPID REGURGITATION.

Hypoalbuminemia can be caused by various conditions, including acute and chronic inflammation, heart failure, malnutrition, hepatic cirrhosis and nephrotic syndrome (1). Low serum albumin is considered an independent predictor of mortality, especially in elderly patients (2). However, albumin or prealbumin are not considered as defining characteristics of malnutrition in elderly (even if Mini Nutritional Assessment is part of the Comprehensive Geriatric Evaluation) because recent evidence show that serum levels of these proteins do not change in response to changes in nutrient intake (3).

CASE REPORT

We present the case of a 87-year-old

woman with a history of numerous cardiovascular diseases (atrial fibrillation, deep venous thrombosis with repetitive pulmonary embolism, severe pulmonary hypertension and chronic congestive heart failure) and thyroid hyperfunction (with normal function under medication). She was admitted in the Geriatric Clinic for aggravating signs of congestive heart failure. She was referred to our clinic for the first time 6 months previously. Ever since, she is under adequate diet and chronic medication: diuretics, digoxin, aspirin and carvedilol, which she takes regularly.

Clinic examination and exhaustive investigations were performed in order to diagnose the main cause that induced her present symptoms and the comparative results with previous hospitalization revealed the following: recent onset of pruritus; dysphonia for the last 3 months; progression of tricuspid regurgitation (grade II → grade III on echocardiography); aggravation of hypoproteinemia (45 mg/l → 38 mg/l) and hypoalbuminemia (21 mg/l → 18 mg/l).

Based on these elements, we considered that this episode of heart failure could be due to the following causes: 1. onset of a new medical condition: neoplastic (dysphonia, pruritus), parasitic infection (pruritus), new alteration of thyroid function; 2. new episode of pulmonary thromboembolism (D-dimers were negative); 3. natural evolution of her ischemic cardiomyopathy; 4. aggravation of hypoalbuminemia.

Exhaustive investigations did not detect any of these suppositions, so we concentrated on the possible causes of hypoalbuminemia as risk factor for heart failure other then the heart failure itself:

- intake deficit – the MNA (Mini Nutritional Assessment) was normal and the Comprehensive Geriatric Assessment (ADL, IADL, GDS, sarcopenia test) revealed a normal nutritional behavior;

- protein loosing enteropathy, a medical condition difficult to prove in very old patients; anyway, the aggravation of tricuspid regurgitation could have increased stasis in venous circulation and decreased normal absorption of nutrients;

- deficit of protein synthesis due to hepatic failure, but the liver tests were normal and abdominal ultrasound and CT were within normal ranges; however, liver function could have been modified by increased stasis due to tricuspid regurgitation;

- increased catabolism due to acute/ chronic inflammation (in our case we considered cancer, tuberculosis, hyperthyroidism, acute hepatitis) but we found no data to confirm these suppositions;

- increased losses due to an unknown renal problem, but renal function was normal.

We concluded that hypoalbuminemia was an important factor in the aggravation of heart failure but, in the same time, aggravation of tricuspid regurgitation and severe heart failure were key causes for hypoproteinemia and hypoalbuminemia. These conditions were tightly interconnected and we took these aspects into consideration when devising therapeutical management. We combined high doses of diuretics, adequate doses of anticoagulants and digoxin with intense treatment of hypoalbuminemia (recombinant human albumin, intravenous amino acids and parenteral nutrition) and we registered a good evolution, with significant decrease of symptoms and important amelioration of quality of life.

DISCUSSION

Low serum albumin is an important predictor of clinical outcome and mortality

in elderly patients. For every 10 g/L decrease in serum albumin level, mortality increases by 137% and morbidity by 89% (1). This is why diagnosis of hypoalbuminemia and, more importantly, identification of the causes that led to this condition, are very important for practitioners.

Hypoalbuminemia is quite common in elderly population due to several causes closely related to aging itself (4). Dietary intake deficit is frequently encountered due to:

- Undernutrition, particularly in institutionalized patients. This age-associated physiologic reduction in appetite and food intake, which has been termed "the anorexia of aging," contributes to the development of pathologic anorexia, and is associated with substantial adverse effects. (5);

- Depression-associated anorexia. Even if depression is not an inevitable part of aging, it is definitely more frequent in old people due to several causes (retirement, the death of loved ones, increased isolation, and medical problems). Geriatric Depression Scale (GDS) is also an important compound of Geriatric Assessment and should alert the practitioner if psychological therapy is needed;

- Drug-induced anorexia: antiparkinson agents (levo-dopa), antibiotics (co-trimoxazole metronidazole), diuretics (clopamide), chemotherapic agents (cytarabine, dacarbazine), anti-Alzheimer's agents (tacrine), anticonvulsants (zonisamide) are known for their negative effect on appetite (6);

- Age-induced changes of digestive system, including dental and hepatic functions (1).

Other frequent causes of hypoalbuminemia in elderly patients are: chronic heart insufficiency, liver cirrhosis, nephritic/nephrotic syndrome, and acute or chronic inflammatory syndrome. If liver and renal problems are relatively easy to identify, inflammation is quite a challenge for physicians.

Inflammation, either acute (burns, infections) or chronic (arthritis, dementia, Crohn's disease) are more often associated with vague symptoms as malaise, fatigue and lack of appetite than with classic symptoms such as fever, headaches, chills, muscle stiffness, and fatigue. Chronic inflammation is typically detected with lab tests including C-reactive protein, complete blood count (CBC) and complete metabolic panel (CMP). Sodium level should be reviewed to see if it is low, in which case, the albumin level may be diluted due to overhydration. The source of chronic inflammation could take a while to identify but anti-inflammatory treatment should be considered in order to influence hypoalbuminemia.

There are several mechanisms that lead to hypoalbuminemia in congestive heart failure (7). If the synthesis of albumin is normal, hypoalbuminemia results from an increased volume of distribution (which will increase hydrostatic pressure and favor migration of fluids in interstitium). There are many situations when right heart failure is accompanied by significant stasis in the mesenteric circulation, which would affect protein absorption from digestive tube and protein metabolism in the liver; these additional mechanisms for hypoalbuminemia are even more pregnant when tricuspid regurgitation is associated or aggravated by different risk factors (recent infections, anemia, and hyperthyroidism).

Recent studies (8, 9) found that there are independent associations between anemia, hyponatremia, severe tricuspid regurgitation, low serum cholesterol and reduced serum

albumin; interestingly, body mass index was not predictive of albumin levels; hypoalbuminemia was common among patients with acutely decompensated heart failure and was independently associated with increased one year mortality.

The direct relanshionship between tricuspid regurgitation and severe hypoproteinemia is mentioned by Sekine (10); moreover, Lau (11) considers that they are not only related but the severity of tricuspid regurgitation is responsible for the severity of hypoalbuminemia because of the stasis in hepatic venous circulation and impairment of hepatic protein synthesis. In the same time, hypoalbuminemia may also contribute to the progression of heart failure by favoring myocardial edema, volume overload, diuretic resistance (12) and exacerbation of oxidative stress and inflammation. This was the case of our patient, as the specific heart failure treatment didn't work but only when associated with treatment of hypoalbuminemia.

CONCLUSION

Hypoalbuminemia is frequently encountered in patients with heart failure and is mainly related to the malnutrition-inflammation association. Other causal factors include hemodilution, liver dysfunction, renal and enteral loss. Evidence is growing that hypoalbuminemia independently predicts incident heart failure in elderly patients, as well as mortality in patients with heart failure regardless of left ventricular ejection fraction. We report a case with severe congestive heart failure associated with important tricuspid regurgitation and hypoalbuminemia foe which correct management included removal of subclinical excess of fluid and renutrition. A multidisciplinary approach is needed in order to achieve a good control of the symptoms and a significant improvement of quality of life.

NEWS

IMPORTANT BIOLOGICAL ACTIVITIES OF POMEGRANATE LEAVES

A group of researchers from University of Toulouse conducted a study that evaluated the antioxidant, anti-inflammatory, anti-cholinesterase and cytotoxic activities of different extracts (hexane, dichloromethane, ethyl acetate, ethanol and methanol extracts) obtained from *Punica granatum* leaves. The total phenolic content varied between 8.8 ± 0.3 and 127.3 ± 1.6 mg gallic acid equivalent/g dry weight. Ethyl acetate extract contained the highest value of total phenolics (127.3 ± 1.6 mg gallic acid equivalent/g dw), followed by methanol (85.2 ± 2.4 mg gallic acid equivalent/g dw) and ethanol extracts (82.6 ± 1.5 mg gallic acid equivalent/g dw). The total flavonoids content varied between 1.2 ± 0.05 and 76.9 ± 2.45 mg quercetin equivalent/g dw. The ethanol extract contained the highest level of flavonoids. The distribution of total tannins content in the extracts showed that tannins were highly concentrated in the hexane extract of pomegranate leaves (260.8 ± 11.5 mg catechin equivalent/kg dw). The dichloromethane extract was found to contain the lowest concentration of tannins (63.7 ± 1.7 mg catechin equivalent/kg dw). Anthocyanins content in the pomegranate leaves depended on the extracting solvent. The hexane extract contained the highest total anthocyanins content (3.73 ± 0.02 mg cyanidin-3-glucoside equivalent/g dw). The methanol extract showed good DPPH and ABTS scavenging effects (IC_{50}=5.62 and 1.31 mg/L, respectively). The strongest 5-lipoxygenase (5-LOX), acetylcholinesterase (AChE) and butyrylcholinesterase (BuChE) inhibition activities were determined for the ethanol extract (IC_{50} values of 6.20, 14.83 and 2.65 mg/l, respectively); the best cytotoxic activity against MCF-7 cells was determined for the methanol extract (IC_{50} = 31 mg/L). These important biological activities showed that the methanol extract of *P. granatum* leaves is a natural source of antioxidants and might be used as a natural additive in food and pharmaceutical industries. Further *in vivo* studies should be done (Bekir J, Mars M, Souchard JP, Bouajila J. Assessment of antioxidant, anti-inflammatory, anti-cholinesterase and cytotoxic activities of pomegranate (*Punica granatum*) leaves. *Food Chem Toxicol* 2013; 55: 470-475).

THE PITFALLS OF DIFFERENTIAL DIAGNOSIS OF LUMBAR SPINE EPIDURAL LESIONS – EXEMPLIFICATION WITH TWO PARTICULAR CASES AND A REVIEW OF THE LITERATURE

B.F. Iliescu[1], B.C. Chiriță[1], I. Poeată[1, 2]

THE PITFALLS OF DIFFERENTIAL DIAGNOSIS OF LUMBAR SPINE EPIDURAL LESIONS–EXEMPLIFICATION WITH TWO PARTICULAR CASES AND A REVIEW OF THE LITERATURE **(**Abstract): **Background and study aims**: Lumbar spinal epidural lesions could belong to a wide spectrum of pathologies. However, some cases present with rare conditions that can cause significant neurological deficit and raise serious diagnostic challenges. We present two such cases where the clinical picture and the imaging findings failed to elucidate the actual diagnosis, which came as an intraoperative and pathological surprise. **Patients**: The first case is that of a 78 years old male that presented for low back pain, bilateral S1 radicular sciatica, paraparesis, and difficulty walking. The neurologic exam showed the absence of the rotulian reflexes bilaterally, and a partial sensory loss in the crural dermatomes. The MRI showed an epidural mass, contrast enhancing at the L1-L2 level, suggestive for an extraxial tumor. The second case is that of a 62 years old woman that presented for a hyperalgic sciatica involving the right S1 root with parestesias in the corresponding dermatome. MRI showed a cystic, contrast enhancing lesion in the L5-S1 recess, mimicking a cystic neuroma. Both patients underwent surgery and histopathological exams were performed from the excised pieces. **Results**: In the first case the surgery resulted in complete removal of the pathological process and histopathological result returned chronic organized hematoma, concordant with the intraoperatory aspect. The evolution was good. In the second case the histopathological result came back as pulpous disk. Again the evolution was good with complete neurological recovery. **Conclusion**: In the presence of an epidural mass with clear clinical symptomatology, rare entities like chronic epidural hematoma or posterior migrated disk material should be always considered as a differential diagnosis in patients with suspicion of extradural chronic compressions. In these cases, only the intraoperatory and histopathological exams can provide a clear diagnosis. **Keywords**: SPINAL, EPIDURAL, DIFFERENTIAL DIAGNOSIS.

Extradural spinal lesions fall within the general classification of traumatic, infectious, neoplastic, developmental, or degenerative pathologies. However, rare cases present with atypical imagistic findings that leave the correct pathological diagnosis to intraoperative and microscopy exam. Significant symptomatology involving the *conus medularis* and the lumbar-sacral roots make these lesions surgical emergen-

cies. For example, acute epidural hematoma is a common complication in spinal surgery (1, 2), but those that result in a neurological deficit are extremely rare (0.1 %) (3). Chronic epidural hematoma is on the other hand very rare (4). The clinical features of a chronic lumbar epidural hematoma may be similar to those of a herniated disk or to those of lumbar spinal stenosis. We present two cases treated in our department recently that we believe strongly illustrate the polymorphism of epidural lesions and the consequent pitfalls of a correct diagnosis in the presence of a lumbar spinal epidural lesion.

CASE 1

The first case is that of a 78 years old male that presented for low back pain, bilateral S1 radicular sciatica, paraparesis, and difficulty walking. Neurological examination at admission showed paraparesis with a sensory loss at the L1 level, absent knee and ankle jerk reflexes. Babinski sign was negative on both sides. No sphincter dysfunction was found.

We performed a MRI exam with contrast enhancement that revealed an epidural mass at L1-L2 level medial-lateral to the left, occupying more de ¾ of the spinal canal at its largest (fig.1). It showed inhomogeneous contrast enhancement, and radicular and *conus medularis* compression.

The patient was operated for prostate adenoma, 2 years before and 8 months before presentation (with normal PSA value 3 months before), both surgeries performed under epidural anesthesia. As co morbidities we learned that the patient also has rheumatoid polyarthritis stage II, operated inguinal herniation, obesity, mild thrombocytopenia.

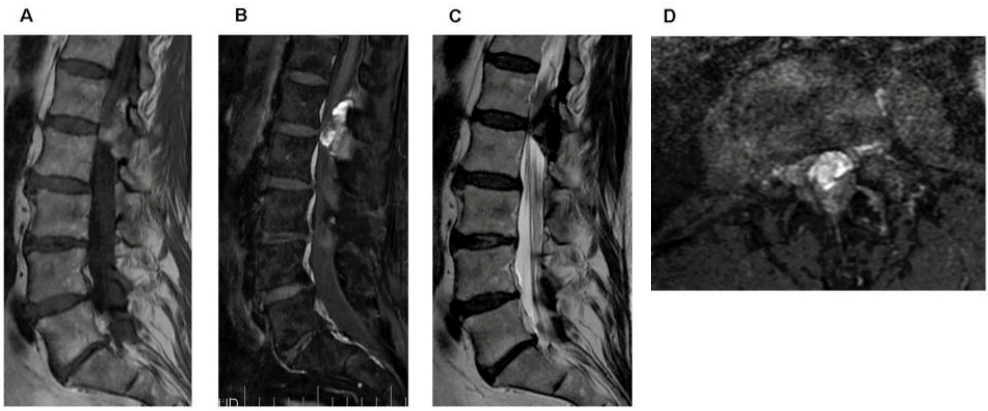

Fig. 1. Preoperative MRI findings in case 1. Sagittal T1 before (A) and after (B) contrast administration showing the cystic lesion at the L5-S1 level with ring-like enhancement. C) the axial enhanced T1 aspect of the lesion.

Postoperatively the neurologic symptomatology remitted except for the sensitive symptoms and the patient was discharged to the rehabilitation clinic for further treatment.

A standard midline posterior approach was chosen and an L1 laminectomy was performed to expose the spinal canal. During the surgery, the dural sac was found to be compressed by a well circumscribed, red-grayish lesion, located in the left poste-

ro-lateral space of the vertebral canal with no adhesions to the nerve roots, but moderately adherent to the dural sac. Under magnification, the lesion was incised, and it contained an isolated well-formed chronic hematoma that appeared to be under pressure (fig. 2). Excision of the thick capsule was performed and the posterior part of the vertebral body was exposed. We observed no disc herniation at the L1–L2 level.

Histopathological examination reported a chronic encapsulated hematoma with reparative fibrous tissue without evidence of malignancy.

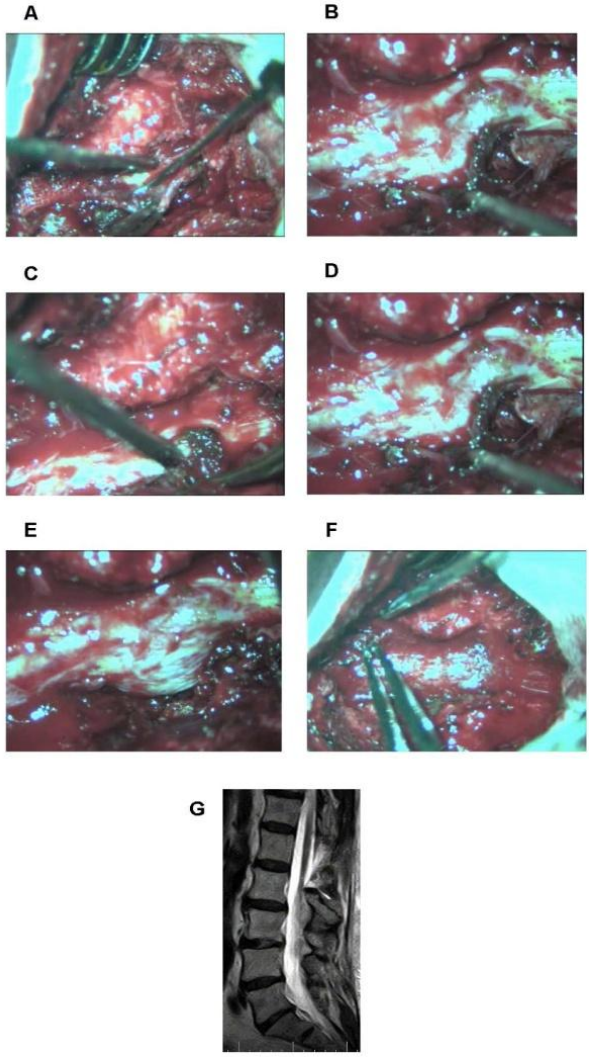

Fig. 2. Intraoperative findings in case 1. A) The pathological mass in the extradural space after cyst content expression (A), during dissection (B) and at the discovery of the dural sac (C). D-E) conjunctive adherences to the dural sac, during dissection. F) final aspect of the dural sac and spinal canal.

CASE 2

The second case is that of a 62 years old female who presented to our department complaining of hyperalgic sciatica of the right S1 root, with paresthesias in the corresponding dermatome, progressive for 1.5 months, after an initial crisis 4 months prior to presentation, self-limited. The neurologic exam showed superficial hypoesthesia on the right S1 dermatome and an achilean reflex of lower amplitude. The conservatory treatment had very little effect on the symptomatology. From the patient's history the only relevant finding was a lumbar trauma 4 months ago (falling down the stairs).

We performed a MRI of the lumbar spine which showed a cystic lesion at the level of L5-S1 foramen, attached to the anterior aspect of the articular process of S1 vertebra (fig. 3A). The finding made us complete the MRI investigation after contrast medium enhancement. The lesion was enhancing circumferentially, keeping the cystic aspect (fig. 3B).

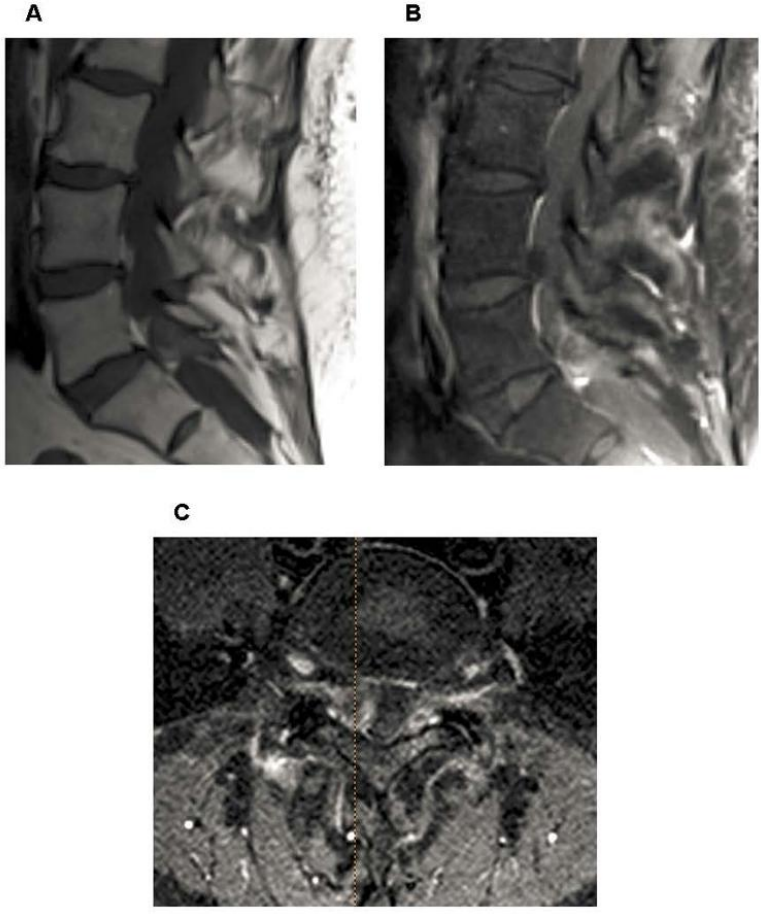

Fig. 3. Preoperative MRI images of case 2. Sagittal planes of native T1 (A), T1 after contrast enhancement (B), and T2 (C) demonstrating the mass occupying lesion at L1-L2 level with heterogeneous contrast enhancement situated in the posterior compartment of the spinal canal. D) axial view of the lesion on enhanced T1-weighted image.

With an unclear clinical and imagistic diagnosis we went on with surgery. We approached the contents of the lumbar canal at L5-S1 level through a standard posterior approach with L5 hemilaminectomy. The bony resection exposed a canal with an unusual aspect. *Ligamentum flavum* was undistinguishable and the canal was filled with a fibrous conjunctive slightly hemorrhagic mass. Under the microscope, at the attempt to find a plan of dissection laterally a brownish fluid was expressed from a false cavity. The dissection continued of what appeared to be a conjunctive cyst till the complete removal of pathologic material and complete exposure of the free dural sac (fig. 4). The pathological exam returned the result of degenerated pulpous disk.

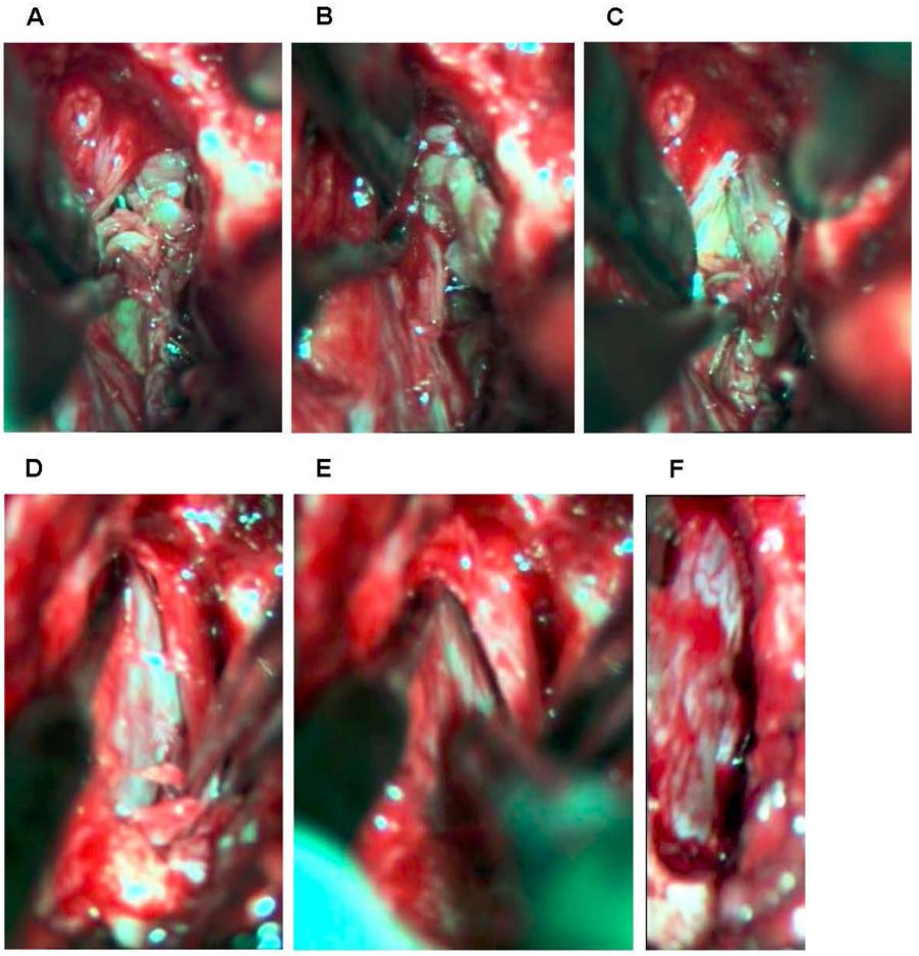

Fig. 4. Intraoperative findings in case 2. A) Initial aspect after canal exposure with capsule dissection. B) Opening of the capsule reveals an organized chronic hematoma. C-E) dissection and excision of the chronic hematoma. F) Final aspect of the spinal canal and dural sac. DISCUSSION

Epidural lesions of the lumbar spine belong to a variety of pathologies and can occur from a variety of situations. Although the tumoral pathology has by far the highest incidence, rare instances can occur and can generate serious difficulties in differential diagnosis. Chronic epidural hematomas in this region in particular seem to have a polymorphic imaging behavior, leading to preoperatory misdiagnosis and, consequently, intraoperatory surprises. They represent extremely rare lesions (0.1 %), being most commonly associated with multilevel surgery, coagulopathies, neoplasia, post lumbar puncture, or the use of high doses of anticoagulant medication (5).

Albeit our first case presented with a recognized risk factor in his history (lumbar puncture for epidural anesthesia) two particularities stand out and prone to discussion. First, the level of the hematoma is 1-2 levels above the level of the puncture. Secondary, the size of the hematoma does not correlate with the symptomatology. It became symptomatic just recently, after more than four months of complete clinical silence, in the case of a clear chronic organization. This divergence might suggest that we may very well be in the presence of a spontaneous chronic lumbar epidural hematoma with a second rebleed that decompensate the initial asymptomatic hemorrhagic collection. It seems to be more likely that the appearance of chronic hematomas occurs in the *conus medullaris* because at this level there are higher pressures in the spinal cord and their arterie (6). The suggested explanation implies that tearing of the epidural veins occurs during intense exercise, which increases the thoracic or abdominal pressure. It is known that the epidural blood plexus volume and pressure depend on the summation of the blood output between intracranial, intrathoracic and intrabdominal blood flow changes (4). Other authors estimate that the hematomas come from an arterial source (7). Graziani et al. (8) proposed as a possible cause for these spontaneous hematomas an epidural cavernous hemangioma.

Posterior epidural disc migration on the other hand is as well a very rare event. Many differential diagnoses are possible in the posterior epidural space other than disc disease. Diagnosis of posterior migrated disc fragment with subtle clinical findings, even though the free fragment has to pass through many anatomical barriers including the nerve roots, poses a clinical challenge. Many differential diagnoses should be kept in mind. MRI findings (especially with contrast enhancement) are useful yet could tell a different story and leave the correct diagnosis to intraoperative tissue sample and microscopy.

Our first case represents a very particular case where an unusual posterior migrated disk and lumbar trauma working together in generating a very particular imagistic and intraoperatory finding. Although known as possible, even if rare, the repeated lumbar trauma was the trigger for subclinical hemorrhages within the yellow ligament and in its vicinity. As a result the disk-ligament-blood complex evolved into a conjunctive mass with liquid content (containing blood byproducts). The clinical picture of clear S1 sciatica was the only indication of a possible herniation; however the MR findings were far from such an instance. The correct diagnosis was possible just after the histopathological investigation of the resection piece.

The clinical symptoms of an epidural hematoma can be similar to those found in

disc herniations, spinal stenosis or spinal tumor (9). A ventrally located hematoma should be differentiated from a posterior longitudinal ligament cyst as described by Toussaint (10). The MRI images of a hematoma can simulate an intracranial tumor or a neurinoma.

CONCLUSION

Although not an unusual location for pathological processes, the lumbar epidural space can be the scene of rare and highly atypical pathologies. In the presence of an epidural mass with clear clinical symptomatology, rare entities like chronic epidural hematoma or posterior migrated disk material should be always considered as a differential diagnosis in patients with suspicion of extradural chronic compressions. In these cases, only the intraoperatory and histopathological exams can provide a clear diagnosis.

METACHRONOUS LUNG CANCER - CASE PRESENTATION (Abstract): Multiple primary tumors can be synchronous when detected simultaneously or metachronous when detected after a variable time interval. We present the case of a 62-year-old female patient with a history of keratinized squamous cell carcinoma of the cervix, stage $T_{3b}N_xM_x$, operated, and treated by chemotherapy and radiation therapy which develops after three years a large cell neuroendocrine carcinoma of the lung detected by imaging. Of major importance in the selection of the optimal therapeutic approach was the accurate determination of the histological type of the metachronous tumor by microscopy and immunohistochemical techniques. The discrete respiratory symptoms and the absence of lung imaging screening accounted for tumor development to an inoperable stage, thus emphasizing the importance of close monitoring of the oncologic patient, thus greatly increasing their chances of survival. **Keywords**: METACHRONOUS CANCER, LUNG CANCER, CERVICAL CANCER.

Multiple primary tumors in a patient are characterized as synchronous, when detected symultanously, or metachronous, when there is a variable time interval between the detection of the first tumor and the detection of a second or even a third tumor. These are the more common as those surviving a form of malignancy live longer (1). The exact causes of the development of other primitive tumors in some oncologic patients are unknown, but radiotherapy and chemotherapy used to treat the first cancer are believed to be predisposing factors.

A recent study (1), using data from the Rhode Island Cancer Registry covering a period of about 20 years, showed a steady upward trend of cancers diagnosed as a second primary tumor from 11.5% to 20.3% in men and 12.8% to 20.7% in women. Of all metachronous cancers, the lung, colorectal, breast and prostate ones account for 54.3% of cases, the average time to diagnosis being 6.5 years in men and 4.8 years in women.

In the literature, multiple primary lung tumors are often described (2-5), but lung cancers metachronous to other organ cancer are less frequent (6).

CASE PRESENTATION

We present the case of a 62-year-old female patient who presented at the Pulmonary Rehabilitation Clinic of the Iasi Rehabilitation Hospital for episodes of inspira-

tory dyspnea, mucus coughing and fatigue, with onset 3 months earlier. The patient was not a smoker, did not drink alcohol, and was not exposed to respiratory hazards.

In her medical history there was a cervical cancer diagnosed in stage $T_{3b}N_xM_x$ three years earlier, treated multisequentially: preoperative radiotherapy and cisplatin chemotherapy, surgery (radical hysterectomy type C_1 and pelvic lymphadenectomy level 2) with favorable postoperative course, followed by postoperative radiation therapy. Pathological examination of the surgically removed specimen established the histopathological type of the cervical tumor - keratinized squamous cell carcinoma.

Physical examination at the time of presentation revealed no significant changes except for some wheezes over the anterior left hemithorax and grade I obesity (BMI = 31 kg/m^2). Laboratory tests revealed a nonspecific inflammatory syndrome (ESR = 54 mm/1h, CRP = 2.82 mg/dl), mixed dyslipidemia (total cholesterol = 225 mg/dl, HDL-cholesterol = 33.43 mg/dl), and impaired fasting glucose (114.1 mg / dl), while ventilatory function tests were within normal range.

Given the patient's symptoms and history, thyroid and abdominal-pelvic ultrasounds were recommended; these showed normal issues without nodular organ lesions or lymphadenopathy. Instead, pulmonary X-ray, the first one performed after genital cancer was surgically removed, showed an ovalary opacity of 7/5 cm, relatively well-defined, located in the left para- and suprahilar areas (fig. 1), which required a chest computed tomography (native and with intravenous contrast).

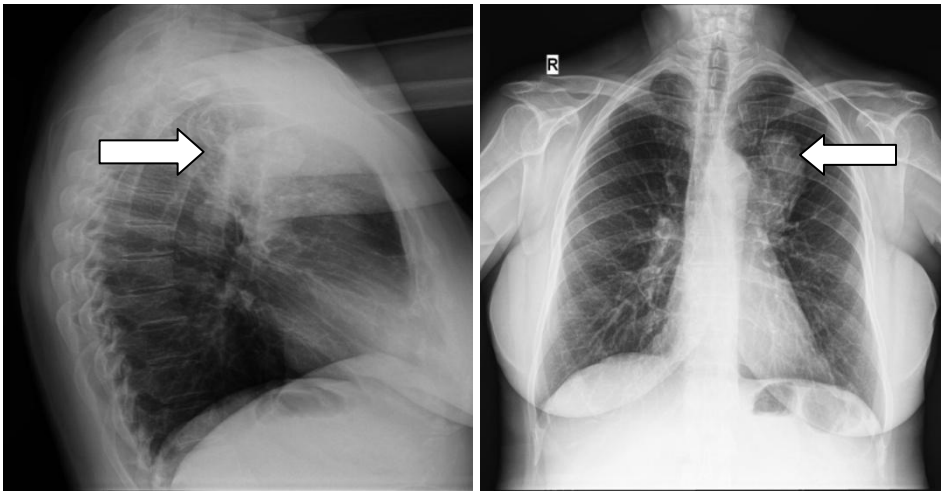

Fig. 1. Chest X-ray
(left – lateral view, right – anterior-posterior view; white arrow – tumoral mass)

The resulting images helped to characterize more precisely the expansive mass as solid, inhomogenous, with areas of necrosis, located in the left upper lobe, with no cleavage plane with the aortic arch and left pulmonary artery (fig. 2). Also, there were no mediastinal lymphadenopathies and pleuropericardial effusion.

In this clinical and imaging context, a late secondary lesion of cervical cancer

was suspected, and the determination of serum squamous cell carcinoma antigen (SCCA) was recommended to guide the diagnosis but the result was within normal range (SCC = 0.2 μg /L). The patient was referred to the Iasi Oncology Clinic and Thoracic Surgery Clinic, with a diagnosis of probable left upper lobe lung primary cancer.

Surgery with curative intent was limited only to taking multiple biopsies from different tumor areas as intraoperatively the lung tumor proved to be adjacent to the large vessels of the left pulmonary hilum, surrounding and discretely compressing them.

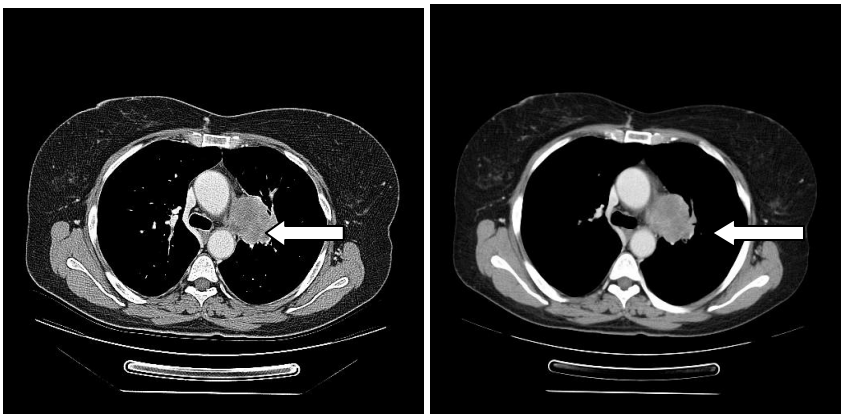

Fig. 2. Chest computed tomography
(left – native, right – intravenous contrast; white arrow – tumoral mass)

Microscopic examination (hematoxylin-eosin, van Gieson) of the collected tumor fragments showed an undifferentiated carcinoma. For an accurate characterization of the tumor multiple immunohistochemical markers were tested (tab.I), the final diagnosis being pulmonary large cell neuroendocrine carcinoma.

TABLE I
Immunohistochemical tumor markers

Immunohistochemical markers	Result
CK7	Zonal positive distribution
CK 5	Positive in very rare cells
TTF-1	Poorly positive zonal distribution
p63	Negative
Synaptophysin	Focally positive
CD56	Zonal positive distribution

The oncologist initiated primary chemotherapy with carboplatin 600 mg and paclitaxel 300 mg, with good immediate clinical tolerance.

DISCUSSION

This case brings up a relatively rare

condition of the oncologic patient who is monitored for locoregional recurrence or metastatic spread, but after clinical recovery, the likelihood of new primary tumors is overlooked. However, statistics show that approximately 20% of cancer survivors develop one or more metachronous cancers (1), requiring a careful, lifelong follow up of these patients.

The patient was diagnosed with lung cancer late and the prognosis was worsened mainly due to the discrete alarm symptoms and also by the absence, for a long time (three years) of a screening chest X-ray.

Of major importance after the discovery of the metachronous lung cancer process was the accurate histological typing of the new tumor in view of optimal selection of therapeutic approach. Initially, serum SCCA was determined, this tumoral antigen being well related with the clinical course of squamous cell cervical cancer (the first tumor in our patient) in terms of recurrent or progressive disease or presence of residual tumor after treatment (7). The very small seric levels suggested that a diagnosis of late pulmonary metastasis of the cervical carcinoma was unlikely. Immunohistochemical techniques, supported by data in the literature (8), were useful in determining the neuroendocrine nature of the second primary lung cancer, poorly differentiated and large cell - type, unfortunately associated with a poor response to chemotherapy (9); also, its perivascular location was contraindication to surgical resection of the tumoral mass.

In conclusion, given the fact that the time interval for the development of metachronous primary tumors in an oncologic patient is unpredictable, but usually takes years, the opportunity for screening and early diagnosis, mainly by imaging monitoring, has not to be neglected, the chances of survival of these patients being thus improved.

ORTHOSTATIC INTOLERANCE AND CHRONIC FATIGUE SYNDROME - POSSIBLE RELATED CONDITIONS (Abstract): The connection between orthostatic intolerance and chronic fatigue syndrome was first introduced in 1995. It was demonstrated that many patients with chronic fatigue syndrome also had some form of orthostatic intolerance. Some studies suggested that dysautonomia may be the common problem in patients with these syndromes. Although these conditions affect an important number of people, especially younger adults, orthostatic intolerance and chronic fatigue syndrome are among the least understood of the autonomic disorders and sustained research is focused particularly on elucidating their pathogenesis and identifying the most effective methods of treatment. **Keywords:** ORTHOSTATIC INTOLERANCE, CHRONIC FATIGUE SYNDROME, AUTONOMIC NERVOUS SYSTEM, DYSAUTONOMIA.

Although it is a condition that affects an important number of people, especially younger adults, orthostatic intolerance (OI) is one of the least understood of the autonomic disorders and it is the subject of a sustained research particularly focused on elucidating the pathogenesis and identifying the most effective methods of treatment. It is known by various names: ,,irritable heart", ,,neurocirculatory asthenia", ,,partial dysautonomia", ,,hyperadrenergic orthostatic hypotension", ,,vasoregulatory asthenia"or ,,soldier's heart". This syndrome has described by Da Costa in 1864, during the American Civil War, affecting young soldiers under physical and mental stress and characterized predominantly by cardiovascular symptoms in the absence of organic suffering (1).

In 1996, following a multidisciplinary conference under the auspices of the American Academy of Neurology and the Autonomic American Society, a brief definition of orthostatic hypotension (OH) was published (2). In Europe, the first guidelines for the management of syncope that included orthostatic intolerance syndromes (OIS) were published in 2001 and reviewed in 2004 by the European Society of Cardiology. To highlight the importance of this problem and because of the increasing number of studies regarding this issue an

update was necessary, the latest version of the guidelines, published in 2009 in the European Heart Journal, was developed in collaboration with the European Heart Rhythm Association, Heart Failure and Heart Rhythm Society Association (1). A few years later, progress in understanding OH and OIS has made it necessary to clarify and expand the original definition, so that in 2011, by a consensus statement endorsed by the American Autonomic Society, the European Federation of Autonomic Societies, the Autonomic Research Group of the World Federation of Neurology and the Autonomic Disorders Section of the American Academy of Neurology the definition, path physiology and clinical forms of the OH were updated and published. Also added were the definitions of two highly prevalent disorders of OI: neutrally mediated (reflex) syncope and postural orthostatic tachycardia syndrome (POTS) (2).

The connection between OI and CFS was first made public in 1995 by Peter Rowe, MD and associates at Johns Hopkins University, who identified a type of OI called neurally mediated hypotension in CFS patients. Since that year, scientists have learned much more about the kinship between OI and CFS.

ORTHOSTATIC INTOLERANCE– CLINICAL, EPIDEMIOLOGICAL AND PATH PHYSIOLOGICAL ASPECTS

Orthostatic intolerance is the development of a set of characteristic symptoms while standing or sitting upright such as dizziness/lightheadedness, pre-syncope, syncope; weakness, fatigue, lethargy, palpitations, sweating, visual disturbances, hearing disturbances (including impaired hearing and tinnitus) and pain in the neck (occipital/paracervical and shoulder region), low back pain, or precordial pain (3, 4). These conditions are a result of inappropriate reflexive bodily responses, regulated by the autonomic nervous system, to compensate the effect of gravity upon the distribution of blood. Predominately in younger individuals, often under the age of thirty five, these syndromes affect more women than men, both children and adults (3, 4, 5, 6, 7, 8, 9, 10).

According to the 2009 syncope management guidelines, there are three clinical forms of OI, and, of all, POTS is frequently associated with chronic fatigue syndrome (CFS). This condition affects mostly young women (11) in a 5:1 ratio over males and most patients are between 20 to 40 years of age (12). They present with severe complaints of OI, but not syncope, symptoms of cerebral hypo perfusion and autonomic over activity that are relieved by recumbence (2), marked increase in heart rate, greater than 30 beats/min, usually to 120 beats/min or higher, and transient systolic blood pressure decrease of more than 20 mm Hg, with recovery within the first minute of tilt (13), criteria that may not be applicable for individuals with low resting heart rates. For individuals aged 12–19 years the required increment is at least 40 beats/minute.

The etiology and pathophysiology of POTS are unknown, but are likely to be heterogeneous. According to Braunwald, major mechanisms are denervation (neuropathic postural orthostatic tachycardia syndrome), deconditioning, and a hyper adrenergic state, each of these three major mechanisms being exacerbated by hypovolemia (12, 13). An important aspect is that the syndrome is also associated with recent viral illness, a limited or restricted autonomic neuropathy, and CFS (2).

CHRONIC FATIGUE SYNDROME– CLINICAL, EPIDEMIOLOGICAL AND PATH PHYSIOLOGICAL ASPECTS

Chronic fatigue syndrome is the common name for a group of significantly debilitating medical conditions. It is characterized by new, unexplained fatigue that lasts for at least 6 months, is unrelieved by rest, is not due to exertion, is not caused by other medical conditions (14) and may be worsened by physical or mental activity. It is also known as chronic fatigue immune dysfunction syndrome, myalgic encephalomyelitis, post-viral fatigue syndrome or by several other terms.

Although biological, genetic, infectious and psychological mechanisms have been proposed, the etiology of CFS is not clearly understood and it may have multiple causes.

We know that symptoms may vary in number, type, and severity from person to person and, unfortunately, there is no specific diagnostic laboratory test or biomarker for chronic fatigue syndrome (15). Although it's name does not express the importance of this illness, CFS brings with it a number of debilitating symptoms: bone-deep fatigue, which is accompanied by other symptoms like sleep difficulties (falling asleep, staying asleep and waking up feeling unrefreshed), concentration and short-term memory problems, joint pain (without swelling), muscle pain, tender lymph nodes, sore throat, and headache. A distinctive symptom is post-exertional malaise, a worsening of symptoms following even very modest physical or mental exertion that can persist for days or weeks. About 25% of people with this syndrome are fully disabled by the illness (16).

Because these symptoms are common with many other conditions and in the absence of any specific laboratory test or biomarker, it is frequently misdiagnosed. Even so, at least one million people in the United States are affected and many others worldwide (17). Another research has shown that CFS is about four times as common in women as men, but it does not make any differences when it comes to age, racial, ethnic and socioeconomic group (18, 19).

We know now that CFS is not a form of depression, and many patients have no diagnosable psychiatric disorder. Also, some abnormalities of the brain have been found in CFS patients using magnetic resonance imaging scans, single photon emission computed tomography and positron emission tomography, predominantly affect the temporal lobes of the brain. Cognitive impairment is common in these patients, the most frequently documented abnormalities being the difficulty in information processing, memory, and/or attention.

CFS patients have disordered expression of genes that are important in energy metabolism.

They have a state of chronic low-grade immune upregulation and substantial evidence of poorly functioning natural killer cells. There is a growing body of evidence of more frequent latent active infection with various herpesviruses and enteroviruses in CFS patients, *Epstein Barr* virus and cytomegalovirus. Other infectious agents can also trigger CFS, including the bacterium that causes Lyme disease, *Giardia duodenalis,West Nile* virus and human parvovirus B19.

Abnormalities of the autonomic nervous system have been found by numerous independent researchers. These include a failure of the body to maintain blood pressure several minutes after a person stands up,

abnormal responses of the heart rate to standing, and unusual pooling of blood in the veins of the legs. Some have also found low levels of blood volume (20, 21).

DISCUSSION

It was demonstrated that many CFS patients (up to 97% in some studies) have some form of OI and it seems to be a particular problem in young people (3, 10, 22, 23, 24). Some studies have suggested that dysautonomia may be the common problem in patients with this syndrome. During tilt-table testing, more than 60% of patients with CFS show abnormal blood pressure or heart rate responses (sudden hypotension or severe bradycardia or tachycardia), along with decreased consciousness (12). OH can result in fainting very quickly after standing and can be diagnosed with a simple in-office test (measuring the blood pressure first while lying down and again upon standing) (3). Unlike patients with OH, in which case the drop of the blood pressure occurs within the first three minutes of standing, chronic fatigue syndrome patients with OI often have a delayed form of OI (25), meaning that the changes do not develop for many minutes after standing, the standard test for acute OH being ineffective in diagnosis. A tilt table test in CFS is considered to be positive if a patient experiences orthostatic symptoms and blood pressure and/or heart rate changes, whether or not he or she faints (3, 5).

There are several hypothesized causes of OI syndrome relevant to CFS, all leading to inadequate blood circulation that may reduce the amount of blood getting back to the heart and brain. Researchers have also identified several physiological abnormalities in CFS patients that are related with autonomic nervous system problems such as POTS. In five studies, adults and adolescents with CFS had elevated heart rates at rest compared to healthy and sedentary controls (8, 10, 23, 26, 27), although two studies found no difference (5). Heart rate further increased when patients underwent a tilt test, a common finding in POTS (3, 8, 10, 27, 28, 29). In addition, three studies - one in adults (27) and two in adolescents (9, 30) found that heart rate variability is significantly reduced in CFS compared to controls. This means that instead of having a heart rate that change appropriately when faced with orthostatic stress, many CFS patients have reduced modulation of their heart rate, suggesting impairment of the autonomic nervous system (9). In contrast, one study of adults with CFS found that heart rate variability is similar to that in controls (3, 30). An important issue is that the effective treatment for patients with OI and CFS must be individualized. Since no cause or cure has been identified, treatment programs should be directed at relieving symptoms, which can allow patients to live almost a normal life (21).

The first line of treatment should be non-medical interventions, such as increasing fluids and salt intake, tilting the head of the bed up a few degrees, wearing compression garments and learning to avoid the situations that can make OI worse (standing in long lines, being in warm environments, and eating large, heavy meals)(4). Also, the therapeutic importance of exercise training and improved physical conditioning is becoming an important strategy for the deconditioned patient (12). Because they often experience guilt, anger, anxiety and depression, it is important to include counseling for emotional and mental health. Educating patients, cognitive behavioral therapy, a form of psychological therapy

often used to treat chronically ill patients are moderately effective treatments (31, 32) that, sometimes, can be useful in treating some patients (30). If these are not effective, doctors may initiate pharmaceutical treatments (4).

Whether relief of any dysautonomic symptoms in these patients may relieve the symptoms of fatigue is unclear. In general, treatment for POTS helps greatly to alleviate some symptoms, but rarely fully resolves the CFS (3).

CONCLUSIONS

Further research is required to determine how orthostatic intolerance is involved in chronic fatigue syndrome. It is clear from past studies that orthostatic intolerance is associated with chronic fatigue syndrome, but the degree and meaning of that association is still a focus of vigorous research (3).

NEURO-PROPRIOCEPTIVE FACILITATION IN THE FUNCTIONAL RE-EDUCATION OF IN FACIAL PARALYSIS. A PRACTICAL APPROACH (Abstract): Facial paralysis, in the form of Bell's syndrome, is an acute paralysis of idiopathic origin. Disability in patients with this medical condition is the result of impairment or loss of complex and multidimensional functions of the face like emotion expression through facial mimics, facial identity and communication. **Aim:** This study aimed to present new and improved practical manual techniques in the area of facial neuromuscular facilitations and to review the literature for disability indexes and facial nerve grading. **Material and methods:** We present the practical modality of using neuro-proprioceptive facilitation techniques, such as rhythmic initiation, repeated stretch (repeated contractions), combination of isotonics and percussion, and also report the effects of these techniques in three Bell's syndrome patients which were previously evaluated. **Conclusions:** Recovery from facial paralysis can be a difficult and long lasting process and the utilization of a grading system may help the physical therapist. The effects of this type of therapy may help benefit the patient if the therapist is well trained and familiar with the neurophysiological background. **Keywords:** FACIAL PARALYSIS, PROPRIOCEPTIVE FACILITATION, BELL'S SYNDROM, HAUSE-BRAUCKMANN SCORE

Facial nerve paralysis, because of the dysfunctional problems that occur at the level of a very personal part of patient's body, who gives their personality, needs special consideration. Because speech, mastication, and expression of moods and emotions are based on the ability to move the facial musculature, successful treatment of facial nerve paralysis and especially functional reeducation are a vital concern for the physical therapists (1).

Bell's palsy has an incidence of approximately 20 cases of 100.000 persons and it's considered to be of idiopathic etiology. The onset is sudden, often proceeded by facial dysesthesia, epiphora, pain, hyperacusis, dysgeusia, and decreased function of the lacrimal gland (2, 3).

We found that very few patients with Bell's palsy are referred from the neurology services to physiotherapy centers. Very often, the patients are told to do nothing and that the muscle function and facial expressions will return without any intervention. Patients that are referred to physical therapy are typically treated with elec-

trical stimulation of the facial muscles and exercises with maximal effort. The results of such interventions were less then optimal resulting in the development of mass action or synkinesis (4).

Facial neuromuscular reeducation with tailored exercises for patients had been demonstrated to be effective in impairments related to facial paralysis (5).

MATERIAL AND METHODS

We are presenting a modality of manual stimulation for the reeducation of functional disorders in facial paralysis inspired from the proprioceptive neuromuscular facilitation concept of H. Kabat. This approach was used in clinical settings on Bell's palsy syndrome patients with positive effects on increasing muscle control and overall functionality; we also report the effects of this technique in three Bell's syndrome patients which were previously evaluated.

The techniques utilized in the rehabilitation of facial paralysis are tailored and executed specifically for every patient separately taking into account the following lines in the therapeutic conduct: degree of muscle function, functional disability and pain.

The techniques that we have used in managing facial paralysis conditions are: rhythmic initiation, repeated stretch (repeated contractions), combination of isotonics and percussion of tendons or marginal fascia of the muscle.

Rhythmic initiation was utilized in patients who could not perform any movement or when the therapist wanted to teach a motion or improve the coordination of that motion; this is achieved starting from passive range of motion and progressively passing to active range of motion with or without manual resistance. Description: the therapist starts by moving the patient passively through the range of motion using verbal commands to set the rhythm, and at a point in the treatment when the patient can promote movement he will first accompany the therapist and then will move against opposed force from the therapist (6, 7).

Repeated stretch was used at the beginning of the range of motion but also through range in case of muscle weakness and also when required for the initiation of motion, increasing strength and range of motion. Description: the therapist elongates the muscle just at the level when he feels a slight tension of the muscle (especially in flaccid situations) and then gives a "tap" to lengthen the muscle and evoke the stretch reflex; at that point the patient receives a verbal command to move and the therapist is resisting the resulted reflex and voluntary muscle contraction.

Combination of isotonics was performed in the program of rehabilitation at the time when the patient would have voluntary muscle contraction and movement for the following goals: achieving active control of motion, coordination and muscle strengthening. Description: the therapist is resisting the movement of the patient through the active range of motion desired, at the end of which the therapist tells the patient to stay in that position for the purpose of stabilization of the contraction. When the stabilization is achieved therapist tells he patient to allow the part to be moved slowly back (eccentric contraction).

In the functional rehabilitation of facial nerve paralysis is important to know the movement of the principal muscles and how to appropriate stimulate them in such a manner as to obtain the maximum muscular response. In the following photos we are presenting the specificity of manual facili-

tation for different muscles and the afferent explanation.

Stimulation of the frontalis muscle is made by the therapist pushing downwards with a diagonal component of inwards movement. The verbal command is: "Lift your eyebrow up and wrinkle your forehead, be surprised" (fig. 1).

Fig. 1. Stimulation of frontalis muscle

Stimulation of the corugator muscle is made by the therapist pulling upward with a diagonal component of outward movement. The verbal command is: "Pull your eyebrows down, look angry" (fig. 2).

Stimulation of orbicularis oculi muscles is made by pulling up the inferior and superior parts of the muscle at the same time with a diagonal component and resisting at the movement of the muscle from the contralateral side to reinforce the weak muscle. The verbal command is: "Close your eyes" (fig. 3).

Stimulation of levator labii superioris and procerus muscles is made by pulling downward superior lip. The verbal command is: "Show your upper teeth and wrinkle your nose" (fig. 4).

Stimulation of zygomaticus major and minor muscles is made by pushing the upper corner of the lip downwards and with a diagonal component of inward movement.

Stimulation of buccinator and risorius muscles is made by pulling the corners of the mouth medially; if the patient will push more interior towards your fingers it will stimulate more the buccinators muscle. The verbal command is: "Pull the corner of your mouth" (fig. 5).

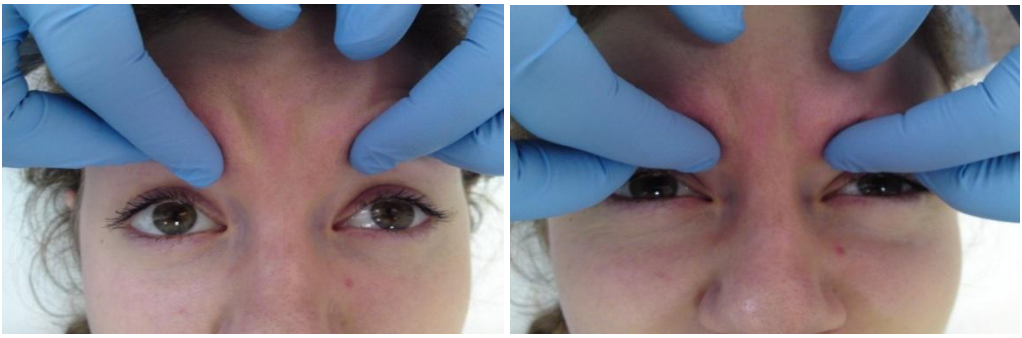

Fig. 2. Stimulation of corugator muscle

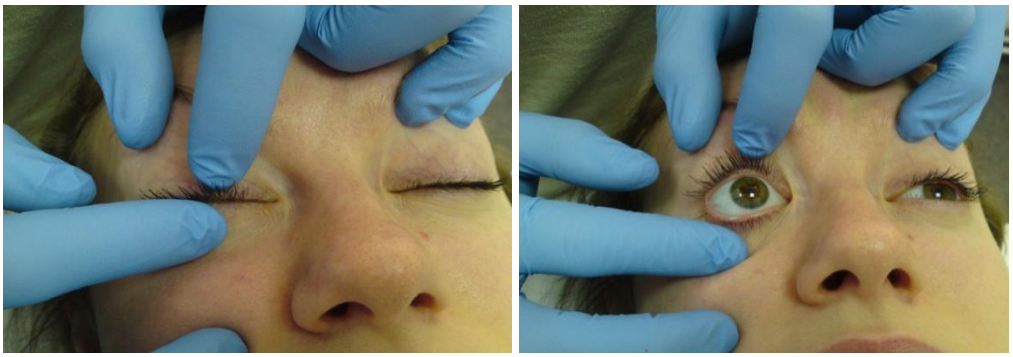

Fig. 3. Stimulation of orbicularis oculi muscle

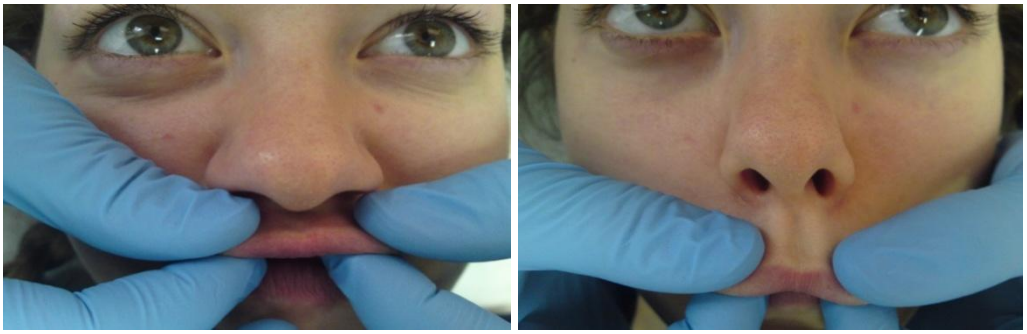

Fig. 4. Stimulation of levator labii superioris

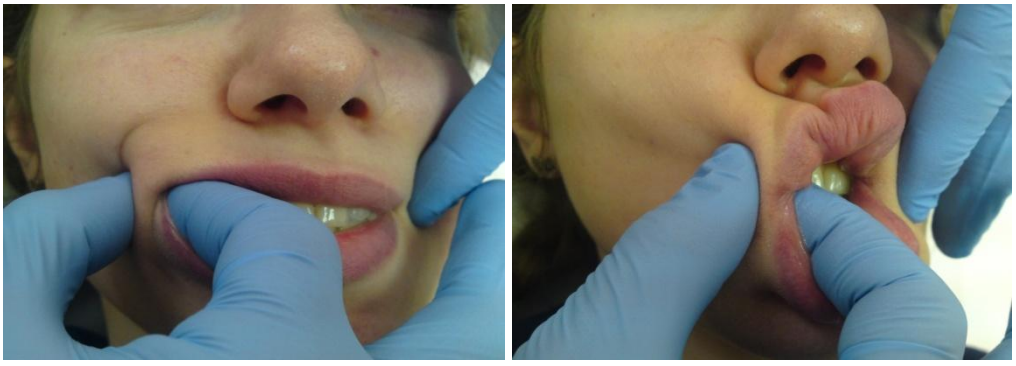

Fig. 5. Stimulation of buccinator and risorius

Stimulation of depressor anguli oris is made by pulling up the corners of the mouth. The verbal command is: "Push down the corners of your mouth. Look like you are sad". Stimulation of oribularis oris muscle is made by pulling outwards the corner of the mouth. The verbal command will be: "Kiss, whistle". This muscle has a great importance in closing the mouth.

CASE PRESENTATIONS

We are presenting three cases of facial paralysis (Bell's syndrom) that were treated at the Physio-kinesitherapy and Rehabilita-

tion Center, Iasi. All the patients that we are presenting were treated with the proprioceptive neuromuscular facilitation (P.N.F.) techniques that we have previously discussed for the duration of 30 sessions of treatment. For the clinical examination of the functional disorders we have chosen, after a review of articles, the Hause-Brauckmann facial nerve grading system which gives a qualitative and a quantitative assessment (8, 9).

S.U. has presented to our clinic on 9.04.2012 with a right facial paralysis caused by the inflammation of the seventh facial nerve. After the clinical examination the qualitative score on Hause-Brauckmann facial grading was V and the quantitative score was 1/8 – 2/8, that meant severe dysfunction with only barely perceptible motion and at rest with facial asymmetry. Characteristics: no movement at the level of the forehead, incomplete eye closure, excessive function of lachrymal glands and slight movement at the level of the mouth.

A.V. has presented to our clinic on 6.07.2012 with a right facial nerve paralysis caused by a car accident with head trauma. After the clinical examination the qualitative score was V and the qualitative score was 1/8 – 2/8. Characteristics: no movement at the level of the forehead, incomplete eye closure with no lachrymal gland action, and slight movement at the level of the mouth.

S.A. has presented to our clinic on 10.09.2012 with a right facial nerve paralysis caused by facial nerve inflammation. After the clinical examination the qualitative score on Hause-Brauckamann scale was graded IV and the quantitative score was 3/8, that meant moderately sever dysfunction with obvious weakness and normal symmetry of the face in rest position. Characteristics: no movement at the level of the forehead, incomplete closure of the eye and asymmetrical closure of the mouth with maximal effort.

RESULTS

After 30 sessions of P.N.F. manual therapy the patients' time of recovery was different from one another and came in different stages.

Patient **S.U.** had a good outcome of its treatment improving his qualitative score from grade V to grade I and the quantitative score from 1/8 to 8/8. The lacrimal gland ceased to work excessively and the blinking of the eyelash came through. The asymmetry of the face at stand position was no more visible and the overall facial expressions were reinstated.

Patient **A. V.** improved his qualitative Hause-Brauckmann score from grade V to grade I and the quantitative score from 1/8 to 8/8. The eyelash started to blink and lachrymal glands resumed their action.

Patient **S.A.** has improved her qualitative score from grade IV to grade I and the quantitative score from 3/8 to 8/8. (tab. I, fig. 6)

TABLE I

Analysis of the Hause-Brauckamann score

Patient name	**Before treatment**		**After treatment**	
	Qualitative score	Quantitative score	Qualitative score	Quantitative score
S. U.	V	1/8	I	8/8
A. V	V	1/8	I	8/8
S. A.	IV	3/8	I	8.8

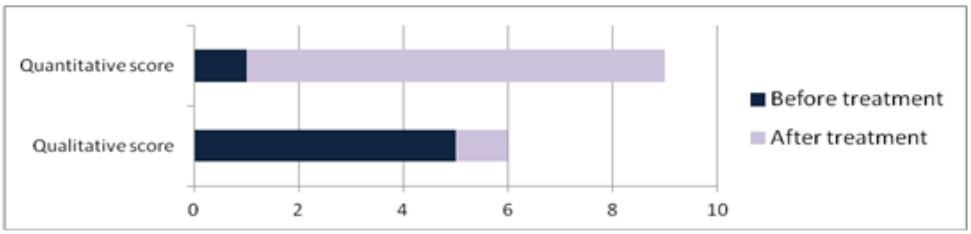

Fig. 6. Evolution of the Hause-Brackmann score

Moreover, because of the negative impact that it has on social integration of the facial paralysis subjects, the patients were more inclined to socialize after the treatment because of the regained conscience over their facial mimics and expressions.

CONCLUSIONS

Recovery from facial paralysis can be a difficult and long lasting process and the utilization of a grading system may help the physical therapist. The effects of this type of therapy may help benefit the patient if the therapist is well trained and knows the neurophysiological background.

Facial paralysis is one of the dysfunctions that actively affect the desire of the patients to communicate in social environments and from this idea it is of most importance for them to be treated their functional disabilities at the level of one part of the body that gives them the identity and their personality.

Furthermore, the success of the program depends on the relation established between the physical therapist and the patient, the perseverance and the motivation that lies behind.

MACRO-CREATINE KINASE SYNDROME AS AN UNDERDIAGNOSED CAUSE OF CK-MB INCREASE IN THE ABSENCE OF MYOCARDIAL INFARCTION. CASE REPORTS (Abstract): When assessing an acute coronary syndrome (ACS) by means of high serum levels of creatine kinase (CK) and its MB fraction (CK-MB), one must keep in mind that there are several other causes for an increase of these markers, such as myocarditis, pericarditis, heart failure, severe aortic stenosis, stroke, renal failure, malignant hyperthermia, Reye syndrome, polymyositis, and borreliosis (1). Also, there are cases when CK-MB is falsely increased due to certain abnormalities that occur in the CK isoenzymes. One such example is the formation of the so-called macro-creatine kinase complexes (macro-CK) that give a false increase of the CK-MB fraction. We report two clinical cases where macro-CK was the cause of apparent increase in serum CK and CK-MB: in a 79-year old male with a history of coronary disease and a 82-year old female with permanent atrial fibrillation. **Keywords**: MACRO-CK SYNDROME, CK-MB FRACTION, ACUTE CORONARY SYNDROME.

Acute coronary syndrome (ACS) includes unstable angina and myocardial infarction. The only way to differentiate between unstable angina and myocardial infarction without ST segment elevation (NSTEMI) reveal myocardial necrosis by dosing biomarkers of myocardial cytolysis. Introduction of cardiac enzymes in clinical practice increased the rate of diagnosis of myocardial infarction by 30%.Cardiac markers are extremely important diagnostic tools especially in the elderly because of atypical clinical forms (insidious onset painless forms, atypical pain) and poor electrocardiographic changes through the predominance of NSTEMI forms.

CK-MB may increase in other diseases than acute myocardial infarction, such as myocarditis, cardiomyopathy, pericarditis, congestive heart failure, close aortic stenosis, stroke, renal failure, malignant hyperthermia, Reye's syndrome, strenuous efforts, trauma muscle, polymyositis, dermatomyositis, Duchenne muscular dystrophy, myoglobinaemia, borreliosis (1).

CK-MB is the most widely used marker for evaluating patients with acute coronary syndromes. Cardiac troponins (I and T) have greater sensitivity and specificity because they are contractile proteins that

are found only in the cardiac myocytes (2). Serial measurements of total CK and CK-MB, associated with troponin measurements may better indicate temporal evolution and infarct size (3, 4).

Creatine kinase (CK) consists of 3 fractions (CK-MM, CK-MB, and CK-BB). A report of total CK / CK-MB> 50% is suggestive for the presence of macro CK complexes (type 1 or 2), resulting in a reaction type Ag-Ac. The occurrence of these immune complexes produces a false increase in CK-MB which can 't be differentiated except by electrophoresis (5).

CASE REPORT I

Patient 1 is known with significant coronary and hypertensive damage ; at the age of 76 years he was performed angioplasty with active pharmacologically on circumflex artery and at the age of 78 years a coronary angiography is carried out again because of prolonged chest pain and occurrence of electrocardiographic changes in dynamics. The coronary angiography revealed the following changes: left coronary artery - LAD stenosis 80% II, 80% ostial stenosis, stent re-stenosis minimum CX I, stenosis 80% GM I, GM II 90% ostial stenosis, right coronary artery - 80% stenosis CD I CD III 80% stenosis, 80% stenosis IVP with surgical myocardial revascularization indication that the patient has timed it.

In April 2012, he was admitted in Geriatric Hospital Clinic "Dr. C.I. Parhon " for precordial pain having angina character and worsening in the last 4 hours before addressing and which partially wakened after Nitroglycerin administration.

Aim at internment: BP = 140/80 mm Hg, FC = 76 b / min, rhythmic, without signs of cardiac decompensation.

Electrocardiogram: sinus rhythm, FC = 70/min, AQRS = -30 °, concentric left ventricular hypertrophy type, ISL = 40 mm

Holter ECG: sinus rhythm throughout the recording

Echocardiography: significant left ventricular wall hypertrophy, SIV = 16 mm, EF = 60%, without hypo-kinetic areas.

Of laboratory results note: total CK = 245 U / l, CK-MB = 226 U / L, troponin T hs = 11 ng / ml (normal: 0-14 ng / ml), SGPT = 30 U / L, SGOT = 31 U / l, LDH = 175 U / l, glucose = 98 mg%.

Because of increased CK-MB, troponin T hs normal, ratio CK / CK-MB> 50%, without significant electrocardiographic abnormalities dynamic and echocardiographic appearance's CK electrophoresis was performed (tab. I). Suspected a false increase in CK-MB. Macro CK Complex has been identified type 1 (1.56 micromol / SL), total CK = 2.5 (normal: 2.85 micromol / SL), CK-MB = 0 micromol / sL (normal: <0.1 micromol / SL), CK-MM = 0.94 micromol / sL (normal: <2.85 micromol / SL), CK-BB = 0 micromol / sL (normal: 0) (tab I, fig. 1, 2).

TABLE I

Results of CK izoenzyme electrophoresis in patient 1

	Patient values	**Normal values**
CK	2,5 µmol/sl	< 2,85 µmol/sl
CK-MM	0,94 µmol/sl	< 2,5 µmol/sl
CK-BB	0 µmol/sl	0,00 µmol/sl
CK-MB	0 µmol/sl	< 0,1 µmol/sl
Macro CK	1,56 µmol/sl (62% of CK)	0 µmol/sl

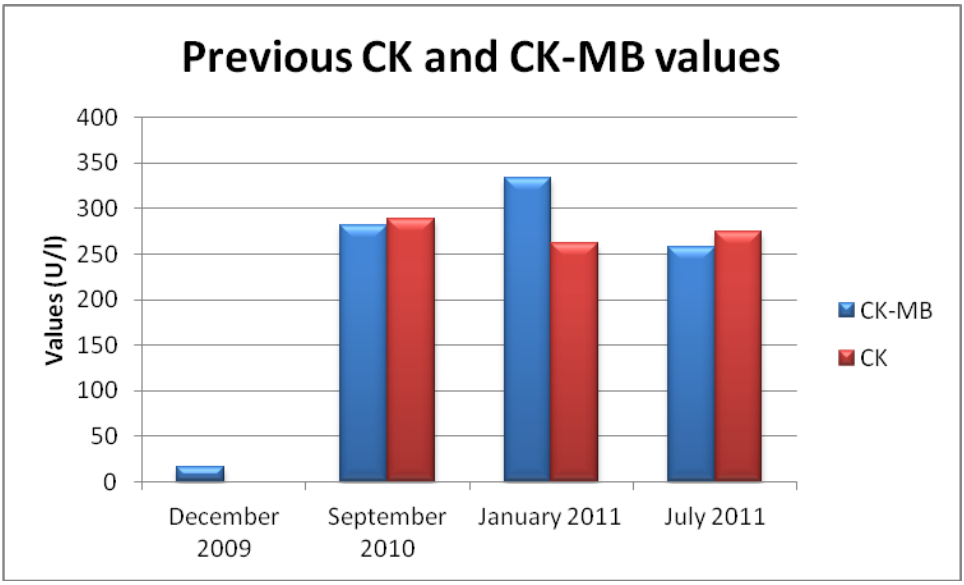

Fig. 1. CK and CK-MB values during previous hospital stay.
Values in 2009 are previously recorded PTCA

CASE REPORT II

Patient 2, well known hypertensive with permanent atrial fibrillation and heart failure NYHA class II left side is admitted for dyspnea at minor efforts occurred two days ago due to psycho-emotional stress. Associates prior atypical chest pain, with emphasis on compression onset 24 hours ago.

Aim at internment: BP = 150/90 mm Hg, FC = 110 / min.

Electrocardiography: Atrial fibrillation, FCM = 104/min, AQRS = 30°, negative T waves in V1, V2.

Echocardiography: EF = 50%, SIV = 11 mm, without hypo-kinetic areas without pericardial fluid, VCI completely inspiratory collapse.

From the laboratory results its is noted: total CK = 248 U / l, CK-MB = 274 U / L, troponin T hs = 17 ng / ml, SGPT = 36 U / l, ALT = 28 U /l.

CK s electrophoresis was performed as in the case of the first patient. It has been identified macro CK complex type 1 (4.33 micromol / sL) = 4.79 total CK, CK-MB = 0 micromol / SL, CK-MM = 0.46 micromol / SL, CK-BB = 0 micromol / SL (tab II, fig. 2).

TABLE II

Results of CK izoenzyme electrophoresis in patient 2

	Patient values	**Normal values**
CK	4,79 µmol/sl	< 2,85 µmol/sl
CK-MM	0,46 µmol/sl	< 2,5 µmol/sl
CK-BB	0 µmol/sl	0,00 µmol/sl
CK-MB	0 µmol/sl	< 0,1 µmol/sl
Macro CK	4,33 µmol/sl (90% of CK)	0 µmol/sl

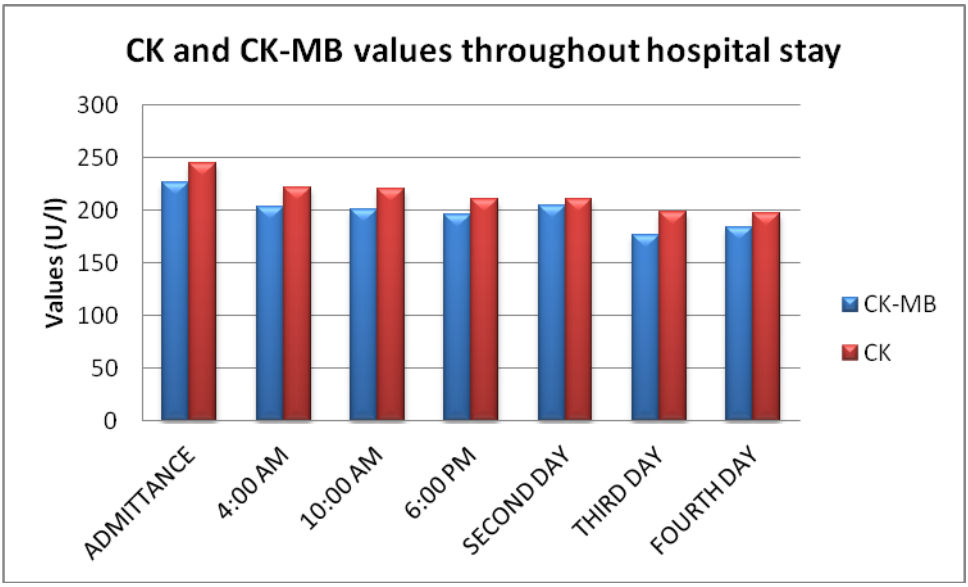

Fig. 2. CK and CK-MB values throughout hospital stay

DISCUSSION

In both cases one can notice a large increase in CK-MB values that could not be explained by acute myocardial ischemia or other common causes of this enzyme increase. Analyzing the previous documents of patient 1 reveals a constant value increase of CK-MB. The only normal value was recorded only in 2009 after stent angioplasty. On the internment in January 2011 and August 2011 the lowest CK-MB value was 125 U / l despite vigorous treatment, properly administered.

A report of total CK / CK-MB> 50% is suggestive for the presence of macro CK complexes. The occurrence of these immune complexes produces a false increase in CK-MB can t be differentiated except with electrophoresis. The presence of macro CK complex still doesn't have a precise use being possible to increase in many other diseases (6).

There are two types of macro CK: type 1 and type 2. Macro CK type 1 occurs via antigen-antibody reaction type between CK-BB and IgG or, less commonly, between CK-MM and IgA (7, 8). Macro CK type 1 (incidence = 0.45% - 1.2%) occurs in hypothyroidism, autoimmune diseases, cancer, myositis, cardiovascular disease and even apparently healthy individuals. It is more common in women and in people over 70 years (9). Macro CK type 2 (incidence = 0.5 - 3.7%) is close to home and migrate mitochondrial CK-MM band. In more severe disease than type 1 appears: malignancy (most commonly colon or prostate cancer) and severe liver disease with a poor prognosis (10).

Macro CK complex appearance does not determine great increase value of total CK (<500 U /l). It should be suspected a false increase in CK-MB in the presence of atypical symptoms of acute ischemia, lack of electrocardiographic changes, echocardiographic and persistent increases regardless of the therapeutic scheme administered (11).

Growth of these enzymes, with a total CK report /CK-MB under 5% is suggestive for non cardiac muscle damage. Troponin specificity and sensitivity is higher than CK-MB determination. Troponin T hs shows frequently increased values than CK-MB in the absence of acute coronary ischemia therefore it is important to determine its dynamics. Any significant increase in intraventricular pressure can lead to abnormal Troponin T hs without myocardial infarction. In patient 2, the slightest increase of Troponin T hs at interment with normalization in the next determination was interpreted in the context of heart failure and atrial fibrillation with fast frequency.

There are few cases of this type reported in literature. Among these, some associate the presence of this syndrome with digestive disorders such as Crohn's disease or ulcerative colitis (12) or persistent diarrhea (13). In other reports it has been noticed associations with cancer (14) or myopathies (15). Rosa Jimenez & et al (16) presents a series of 7 cases with macro-CK type 1 syndrome, of which 3 cases had a history of cardiovascular disease and the rest were not known. Patients reported in this article are the first reported in Romania with macro-CK syndrome.

CONCLUSIONS

Highlighting cases of macro CK is useful for avoiding invasive investigations and unnecessary treatments. The particularity of the first patient case consists in a false increase of CK-MB at a patient with three-vessel lesions and indication for revascularization surgery. The systolic function is maintained within normal limits and poses no arrhythmia at ECG Holter monitoring, in significant myocardial ischemia. The particularity of the second case is the combination of a significant increase in CK-MB in the presence of a chest pain caused by musculoskeletal pain (possible intricate pain) and without electrocardiographic changes in dynamics and without echocardiographic hypo-kinetic areas. Electrophoresis Creatine is currently quite expansive investigation and can be suspected the presence of complex macro CK emergency when the total report CK / CK-MB> 50%.

Discrepancy between the values of CK-MB and troponin must raise a question mark for the diagnosis of acute myocardial infarction and the values of these biomarkers must be correlated with clinical examination, electrocardiographic and echocardiographic aspect.

Guidelines for acute coronary syndrome should mention this false increase in CK-MB as a variant of differential diagnosis.

NEWS

A NEW METHOD FOR DETECTION OF BACTERIAL PROTEIN SECRETION

Bacteria interact with host cells through secretion systems which carry proteins through bacterial membrane. Developing methods to monitor bacterial protein secretion can bring new information for diagnostic of bacterial infections. Enzymatic or fluorescent marking of proteins to reveal genes involved in transmembrane export of bacterial proteins can used to study the interaction of bacteria with host cell. A recent study conducted by M. M. Champion and collaborators describe a modified form of bacterial proteomics using a MALDI-TOF mass spectrometer, which directly detects the proteins from whole colonies. This method is able to specifically monitor a special protein secretion system, which is a major virulence determinant in *Mycobacterium tuberculosis, Bacillus* and *Staphylococcus* species. Also this method can be applicable to study other bacterial protein export systems and for the identification of compounds that inhibit bacterial protein secretion (M. M. Champion, E. A. Williams, G. M. Kennedy, P. A. DiGiuseppe Champion**.** Direct Detection of Bacterial Protein Secretion Using Whole Colony Proteomics**.** *Molecular & Cellular Proteomics*, 2012; 11 (9): 596-604).

BIOCHEMICAL AND ULTRASOUND ASPECTS IN CHRONIC VIRAL HEPATITIS C PATIENTS (Abstract): **Aim:** Biochemical and ultrasound investigations in patients with chronic hepatitis C on a 48-week anti-viral regimen. **Material and methods:** A group of 6 patients, 4 women and 2 men, age range 24-61, were evaluated at the beginning of therapy and compared after 48 weeks of peginterferon alfa-2a and peginterferon alpha-2b regimen at doses established by the National Treatment Program approved by the Romanian National Health Insurance House. **Results**: ALT and AST levels have decreased in all patients. The viral load was undetectable in two patients, both females, after 48 weeks of therapy. Ultrasound images showed a decrease in size of the right and left hepatic lobes and portal vein diameter after 48 weeks. **Conclusions**: Inhibition of virus by interferon and ribavirin resulted in the reduction of inflammatory phenomena and regenerative fibrosis noticed after a very long period of time (at least 48 weeks). Further studies performed on larger patient groups are needed in order to better describe all these changes. **Key words**: CHRONIC VIRAL HEPATITIS C, INTERFERON, RIBAVIRIN, ULTRASOUND

In Romania, the average prevalence of hepatitis C in general population is approximately 5%, but it appears to be underestimated. As to mortality rate from chronic liver disease, Romania ranks fourth in Europe with 44.5%ooo deaths, as compared with the European average of 15%ooo.

70 to 80% of hepatitis C infection cases become chronic. Currently, no vaccine is available for hepatitis C (1). The diagnosis is made on elevated aminotransferase levels, antibodies to hepatitis C and hepatitis C virus RNA in the blood and liver biopsy confirming the diagnosis (2).

Careful screening is necessary before starting the treatment to determine the most appropriate approach for the patient. Combination anti-viral therapy with interferon and ribavirin has been the mainstay of hepatitis C treatment. Unfortunately, interferon is not widely available globally, it is not always well tolerated, some virus genotypes respond better to interferon than others, and many people who take interferon do not finish their treatment. This means that while hepatitis C is generally considered to be a curable disease, for many people this is not a reality (3).

Evaluation of treatment possibilities and contraindications, testing of hepatitis C virus genotype, and estimation of side effects are important therapeutic algorithm steps in patients with chronic hepatitis C. The use of subcutaneous peginterferon once a week and oral ribavirin 1000-1200 mg daily is the treatment of choice in these patients (4).

MATERIAL AND METHODS

Our study was conducted on a series of 6 patients with chronic viral hepatitis C, 4 women and 2 men, age range 24-61, evaluated at the beginning of therapy and compared after 48 weeks of treatment with peginterferon alfa-2a and peginterferon alpha-2b at doses recommended by the National Treatment Program approved by the Medical Committee of the Romanian National Health Insurance House.

Patients were assessed biochemically – alanine (ALT) and aspartate (AST) aminotransferase, serologically, and ultrasonographically. Viral markers and viral load, degree of necroinflammatory activity and level of fibrosis, development of complications (necrosis and liver fibrosis), size and other changes in the portal vein, morphological and clinical changes were some benchmarks. Patients were reassessed on completion of treatment (at 48 weeks of starting regimen).

Liver fibrosis was assessed by approved methods (PBH and FibroScan), in limits for chronic hepatitis (F1 to F3 Metavir score): of the six patients one had F1; four F2; and one patient F3 score.

RESULTS

Biochemical investigations. Comparatively, ALT and AST levels, baseline and after 48 weeks of anti-viral treatment, decreased in all study patients, but the most important decrease in ALT level was from 43 to 24 UI/ml (case 5, female, age 61) and in AST from 30 to 18 (the same patient); the smallest decrease was from 86 to 79 for ALT (case 2, male, age 51) and from 71 to 66 for AST (the same patient) (fig. 1, 2).

Viral load also decreased in all hepatitis C patients, but was undetectable in two cases (both females, aged 61 and 24, respectively) at the end of the 48 week- antiviral therapy.

Ultrasound investigations. We followed the size of right and left hepatic lobes (RHL, LHL), which decreased after the anti-viral regimen. The most significant decrease in RHL size was also noticed in case 5, from 124 to 101 mm and the less significant in case1 (female, age 41) – from 138 to 130 mm (fig. 3). Case 3 (male, age 47) showed the most significant decrease in LHL size, from 65 to 50 mm, while in case 1 the decrease was of only 3 mm, from 71 to 68 (fig. 4).

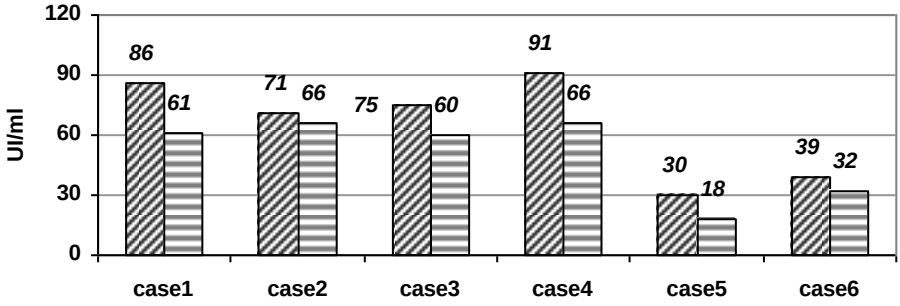

Fig. 2. Decrease in AST levels in treated patients

	case1	case2	case3	case4	case5	case6
before treatment	138	145	147	128	124	129
after 48 weeks	130	135	130	118	101	108

Fig. 3. Decrease in RHL size

	case1	case2	case3	case4	case5	case6
before treatment	71	83	65	85	72	62
after 48 weeks	68	70	50	76	65	50

Fig. 4. Decrease in LHL size

Significant changes in portal vein diameter after 48 weeks of anti-viral therapy were also recorded. A reduction of 1.5 mm was noticed in one case, 1 mm in two; 0.5 mm in one; and no reduction in the remaining two patients (fig. 5).

In all patients, the above-mentioned biochemical concentration levels and diameter values were induced by hepatic distress in the context of liver regenerative fibrosis, the clinical and ultrasound outcomes being moderate (fig. 6).

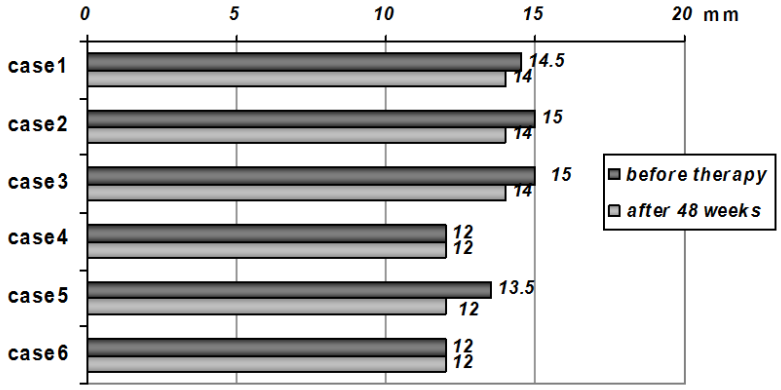

Fig. 5. Decrease in portal vein diameter

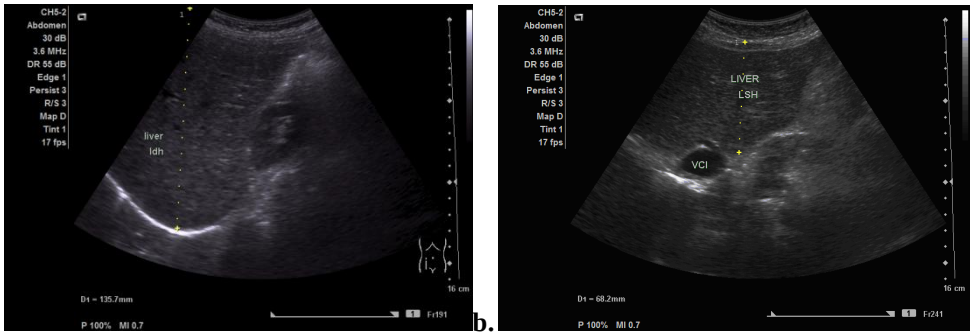

Fig. 6. Ultrasound images at the beginning (a) and after 48 weeks (b) of antiviral treatment (case 1, female, age 41)

DISCUSSION

In a systematic review, Shepherd et al. (5) mentioned that in the two trials testing pegylated interferon plus ribavirin against non-pegylated interferon plus ribavirin the combined percentage of sustained virological response (SVR) was 55%. In the four trials that evaluated pegylated interferon mono-therapy against non-pegylated interferon the combined SVR rates were 31% for pegylated interferon and 14% for non-pegylated interferon. Adverse events have been reported, but they did not differ substantially from levels of adverse events in regimens involving non-pegylated interferon.

Another meta-analysis on chronic hepatitis C therapy by Ford et al. (6) in middle-income countries highlighted that the treatment with pegylated interferon and ribavirin was associated with better outcomes than other regimens, and only 4% of patients included in the meta-analysis discontinued treatment because of adverse events.

Awad et al. (7), in a meta-analysis conducted in 2010, stated that peginterferon alpha-2a significantly increased the number of patients who achieved a sustained virological response (SVR) *vs.* peginterferon alfa-2b. The metaanalysis of adverse events leading to treatment discontinuation in
cluded 11 trials and revealed no significant differences between the two peginterferons. Authors suggested that peginterferon alpha-2a was associated with higher SVR than peginterferon alfa-2b.

Hézode et al. (8) in a study performed on a series of 91 patients with chronic hepatitis C and significant fibrosis (>7.0 kPa) who received therapy with pegylated interferon-α and ribavirin, mentioned that a significant liver stiffness decrease was observed during therapy, which continued after treatment only in patients who achieved SVR.

In a study carried out in South-East Asia, Chavalitdhamrong and Tanwandee (9) showed that during a follow-up interval of about 3 years in 171 chronic hepatitis C patients with SVR after effective anti-viral therapy there were no evident signs of either biochemical or clinical relapse of liver injury in all individuals.

In a multivariate analysis, Vergniol et al. (10) asserted that, whatever the virological response, treatment for hepatitis C was associated with an improvement of FibroScan and Fibrotest values. These non-invasive methods, and especially FibroScan, should be useful for assessing treatment efficacy in clinical trials of new regimens.

CONCLUSIONS

The comparative analysis of the study patients highlighted the homogeneity of the group: all individuals presented criteria for inclusion in a standard therapeutic protocol: elevated ALT and AST levels; liver fibrosis determined by approved methods (PBH and FibroScan), in limits for chronic hepatitis (between F1 and F3 Metavir score); an expected decreasing trend of the above-mentioned parameters during the therapy.

Virus inhibition by interferon and ribavirin led to a reduction of inflammatory phenomena and regeneration fibrosis after 48 weeks of therapy.

Along with treatment, "helper" factors, such as diet and lifestyle - very restricted in some cases, hepatic protective drugs, administration of various plant products, and the so-called sparing social and environmental factors, also contributed to the improvement of follow-up treatment parameters.

NEWS

DENTIN REGENERATION USING DECIDUOUS PULP STEM/PROGENITOR CELLS

During the last decade, tissue engineering has been extensively used in the regenerative medicine. Mesenchymal dental stem derived from teeth are easily accessible multipotent cells with the capacity to differentiate into distinct cell types. Reparative dentin formation is essential for maintaining the integrity of dentin structure during caries or trauma. In this study, it was investigated the stem/progenitor cell-based tissue engineering for dentin regeneration in a large animal model. Porcine deciduous pulp stem/progenitor cells (PDPSCs) were mixed with a beta-tricalcium phosphate (β-TCP) scaffold for dentin regeneration. Different concentrations of PDPSCs were tested to determine the optimal density for dentin regeneration. Aliquots of 5×10(5) PDPSCs in 1 mL resulted in the highest number of cells attached to the scaffold and the greatest alkaline phosphatase activity. PDPSCs were labeled with green fluorescent protein (GFP) and the optimal cell numbers mixed with β-TCP were used to repair pulpchamber roof defects in the premolars of swine. Four weeks after transplantation, GFP-positive PDPSCs were observed in PDPSC-embedded scaffold constructs. At 16 weeks after transplantation, the PDPSCs mixed with β-TCP significantly regenerated the dentin-like structures and nearly completely restored the pulp chamber roof defects. This study demonstrated that the PDPSC/scaffold construct was useful in direct pulp-capping and provides pre-clinical evidence for stem/progenitor cell-based dentin regeneration. Stem cells could be of benefit in development of techiques for regenerative dentistry (Zheng Y, Wang XY, Wang YM, Liu XY, Zhang CM, Hou BX, Wanq SL. Dentin regeneration using deciduous pulp stem/progenitor cells. J Dent Res 2012; 91(7):676-682).

Clinica de Gastroenterologie şi Hepatologie

SOME ASPECTS REGARDING VIRAL HEPATITIDES B AND C. OBSERVATIONS ON PATIENTS TREATED IN THE BACAU COUNTY, BETWEEN 2007 AND 2010 (Abstract): The study aim was to assess some features of samples of patients assisted for viral hepatitis B and C, as well as cirrhosis, and included in a national antiviral treatment protocol. Material and methods. The study considered patients assisted in the medical assurance system in the Bacau County, Romania, during 2007 and 2010. Results. A sample of 1127 patients with chronic viral hepatitides B and C was assisted, from which 154 cases with B virus (13.7%) with a male predominance and 973 with C virus (86.3%) and a female predominance. An increase trend for both hepatitides prevalence was highlighted and a number of non-responders every year (18.1% of total cases). Conclusions. A correct diagnosis and treatment of\cases with chronic viral hepatitis B and C and to have a smaller number of non-responders represent major purposes of specialists in the Bacau County also. **Key words**: VIRAL HEPATITIS B, VIRAL HEPATITIS C, ANTIVIRAL TREATMENT, INTERFERON

*Hepatita virală B (*HVB) continuă să constituie o importantă problemă de sănătate publică pe plan mondial, cu toate că actualmente există mijloace eficiente de prevenție activă. Manifestările care decurg din evoluția autolimitantă sau persistentă a infecției cu virus B, îmbracă un spectru clinic foarte variat, de la hepatita acută cu evoluție rezolutivă la formele fulminante, de la starea de purtător sănătos, la ciroză şi cancer hepatic primar (CHP), respectiv la boli cronice extrahepatice (renale şi cardiovasculare) (1, 2, 3).

Hepatita virală C (HVC) este considerată inițial ca o hepatită transmisă aproape exclusiv (85-90%) prin sânge contaminat, astăzi s-a dovedit faptul că poate să apară şi sporadic la persoane fără antecedente transfuzionale, achiziționată comunitar (2, 4). Dominanta caracteristică a infecției cu VHC este evoluția preponderent persistentă, silențioasă din punct de vedere clinic, cu o tendință marcată de cronicizare şi malignizare. Se aproximează că 50% din infecțiile persistente evoluează spre hepatită cronică, 10-20% din hepatitele cronice trecând în ciroze. Incidența anuală a decompensării cirozelor, decompensări care pot conduce la deces în 2-5% din cazuri (1, 4, 5).

În prezent, există o multitudine de mijloace terapeutice, cu mecanisme variate de acțiune şi eficiență inegală, unele aflându-

se încă în faza de evaluare. În individualizarea tratamentului trebuie să se țină seama de o multitudine de parametri, printre care şi răspunsul imun endogen față de virusurile hepatitice (6, 7, 8, 9).

MATERIAL ŞI METODE

Studiul a luat în considerație un lot de pacienți cu HVB şi HVC, asistați în sistemul de asigurare medicală din județul Bacău, în perioada 2007-2010.

Criteriile de includere au cuprins cele legate de pozitivitatea diagnosticului referitor la prezența hepatitei virale B, C şi / sau D, prezența hepatitei cronice şi / sau a cirozei hepatice în contextul infecției virale, eligibilitatea pentru a intra într-o schemă terapeutică cu interferon şi antivirale, precum şi calitatea de asigurat la CAS Bacău. *Criteriile de excludere* au cuprins infirmarea diagnosticului de hepatită virală cronică.

Culegerea datelor a fost efectuată pe baza rapoartelor statistice existente la Casa de Asigurări pentru Sănătate Bacău, iar prelucrarea şi interpretarea s-au realizat cu ajutorul softului MS Excel şi SPSS 16.0.

REZULTATE ŞI DISCUȚII

1. Unele caracteristici demografice ale lotului studiat. În perioada 2007-2010, în județul Bacău, au fost asistați terapeutic 1127 pacienți cu hepatite virale cronice cu virus B şi C. Dintre aceştia, 154 au fost cazuri cu virus B (13,7%), iar 973 pacienți au prezentat hepatită C (86,3%).

Prevalența cea mai ridicată a fost întâlnită în anul 2010, prin cumularea cazurilor din anii precedenți (fig. 1), incluse în schemele terapeutice comune, la care se adaugă un număr, din ce în ce mai ridicat, de cazuri noi.

Distribuția pe sex arată o predominanță a bărbaților în lotul de cazuri cu HVB şi predominanța netă a femeilor în HVC (fig. 2, 3). De asemenea, tendința este crescătoare, pe seama cazurilor incluse în schemele de tratament, la care s-au adăugat unele îmbolnăviri.

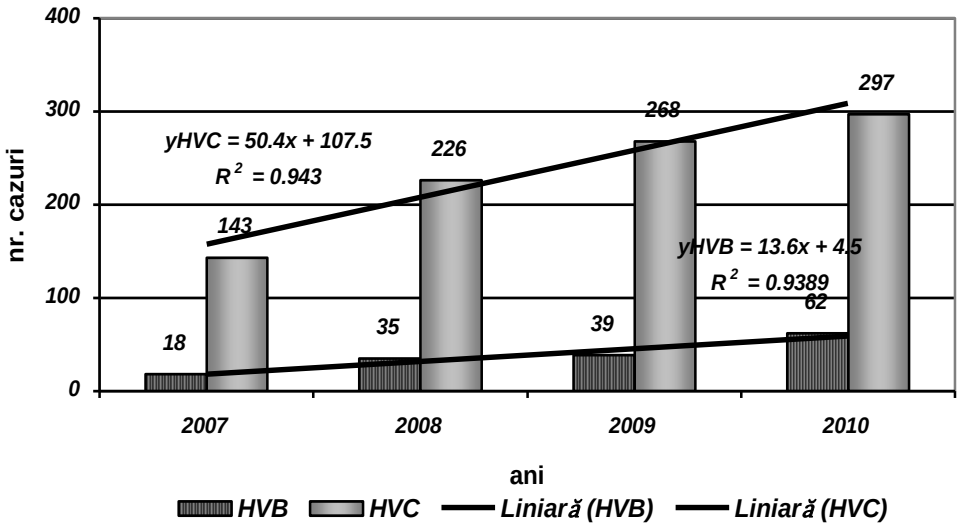

Fig. 1. Distribuția anuală a pacienților cu hepatite virale B şi C, luați în evidență în vederea tratamentului antiviral, în județul Bacău, în perioada 2007-2010

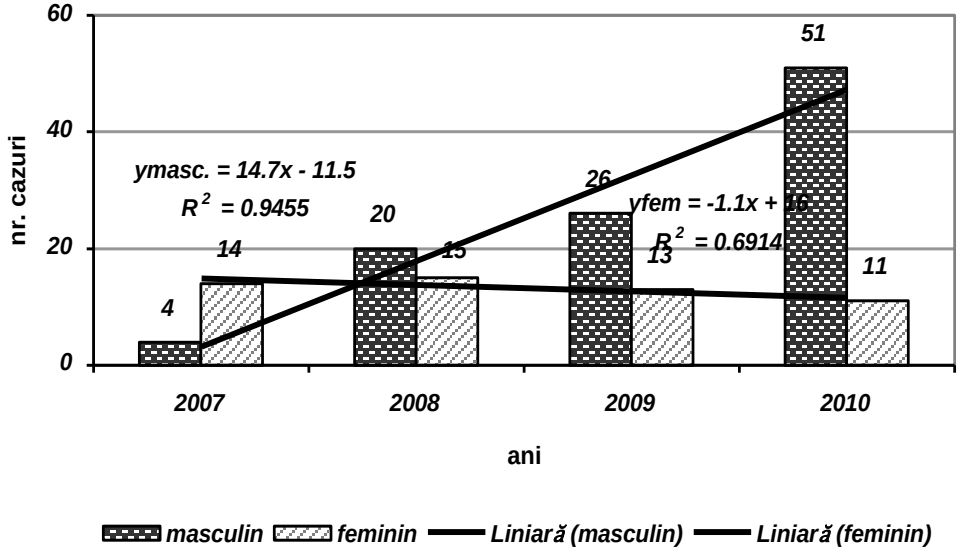

Fig. 2. Distribuția anuală şi pe sex a pacienților cu hepatită virală B cronică

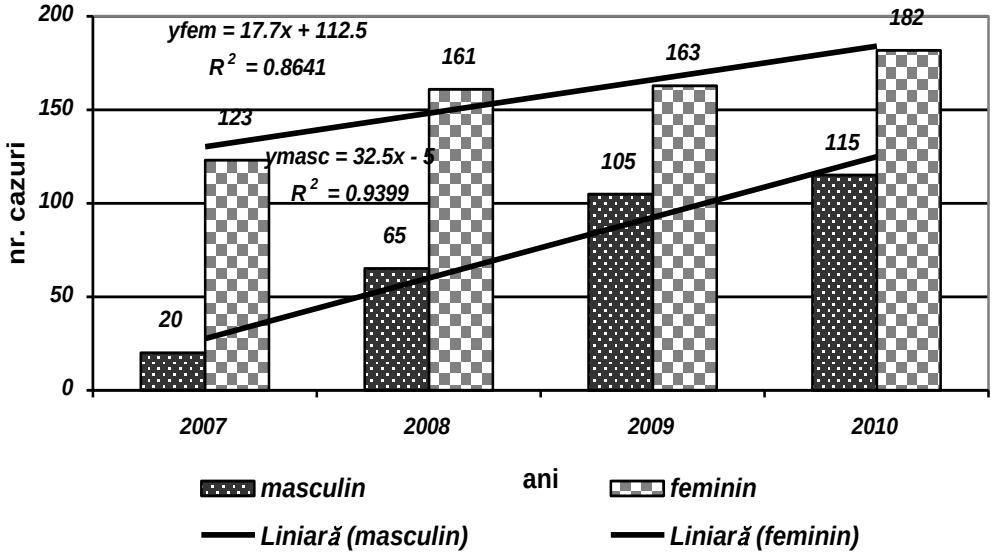

Fig. 3. Distribuția anuală şi pe sex a pacienților cu hepatită virală C cronică

Dacă pentru HVB, s-a observat o uşoară tendință de scădere a incidenței bolii la sexul feminin, pentru HVC, atât la bărbați, cât şi la femei, tendințele au fost de creştere semnificativă. Situația înregistrată se poate explica prin existența în populația

judeţului Bacău a unui număr în creştere de surse de virus C, ceea ce presupune un risc crescut de apariţia unor noi cazuri în anii următori.

2. Descrierea lotului de studiu, pe ani calendaristici. În ***anul 2007***, au fost incluşi în lot 18 cazuri de HVB, dintre care 4 bărbaţi şi 14 femei (raportul M/F = 0,28), iar cu HVC, 143 pacienţi, dintre care 20 de sex masculin şi 123 feminin (raportul M/F = 0,16). S-a observat predominanţa femeilor, în special pentru HVC, fapt care poate fi explicat printr-o frecvenţă mai mare a modalităţilor de transmitere (investigaţii paraclinice invazive) a virusului hepatitic C, în populaţia feminină. Datele noastre concordă cu cele de la nivel mondial, referitoare la distribuţia pe sex a HVC (1, 2, 4).

La lotul de 161 cazuri s-au adăugat 12 pacienţi cu ciroză hepatică, dintre care 5 bărbaţi şi 7 femei (tab. I). Vârsta medie a lotului studiat a fost de 50 ani şi 65,2% peste.

TABELUL I

Distribuţia pe sex a cazurilor de hepatite virale şi ciroze, incluse în tratament, în anul 2007

Categorii	Nr. cazuri	Bărbaţi		Femei	
		Nr.	%	Nr.	%*)
HVB	18	4	22,2	14	77,8
HVC	143	20	13,9	123	86,1
Ciroză hepatică	12	5	41,6	7	58,4

*) pentru valorile mai mici de 10, proporţiile sunt orientative

Au fost incluşi în tratament încă 84 pacienţi cu HVC, dintre care 75% în stadiul F2, 15% - F3 şi 5% - F4. Asocierile virale s-au evidenţiat numai cu Ag HBs – 14 cazuri din care 2 nonresponderi; B + C + D – niciun caz; B + D – 9 cazuri din care 1 nonresponder.

În ***anul 2008***, a fost adăugat, la tratamentul standard, şi Entecavir. Pentru HVB, s-a utilizat doar interferonul, iar pentru pacienţii cu HVC, asocierea interferon cu ribavirină. Din lotul de 35 cu HVB, 20 (57,1%) au primit tratament cu Entecavir (raport M/F = 17/3), iar ceilalţi 15 pacienţi, au fost trataţi cu interferon standard (3 x 10 M UI / săptămână) (10, 11, 12).

În studiu au fost incluşi, de asemenea, 226 pacienţi cu HVC, 65 bărbaţi şi 161 femei. Astfel că cele 71 cazuri noi de boală au determinat o rată de atac (incidenţă specifică) pentru HVC, în judeţul Bacău, pentru anul 2008, de 31,1%.

Evaluarea asocierilor virale a evidenţiat: pacienţi cu AgHBs prezent – 20 dintre care 5 au finalizat tratamentul; B + D – 10 pacienţi, cu 6 cazuri cu tratament finalizat; B + C – 5 cazuri din care toate rămase în schema terapeutică; B + C + D – niciun caz (tab. II). În acest an, 31 (11,8%) au fost pacienţi nonresponderi.

TABELUL II

Asocieri virale înregistrate la pacienţii cu hepatită cronică, în anul 2008

Virusul	Nr. total cazuri	Din care, cu tratament finalizat
Ag HBs prezent	20	5
B+D	10	6
C	226	0
B+C	5	0
B+C+D	0	0

În ***anul 2009***, au fost urmărite 39 cazuri de HVB, 26 bărbaţi şi 13 femei (raport M/F = 2). Cu HVC cronică, au fost 268 pacienţi, 105 bărbaţi şi 163 femei (raport M/F = 0,64). Din acest lot, un număr de 103 (38,4%) cazuri au fost scoase din schema terapeutică, fiind considerate *nonrespon-*

deri, astfel: la 4 săptămâni – 24 (23,3%); la 12 săptămâni – 76 (73,7%); la 24 săptămâni – 3 (4%).

Asocierile virale au fost: cu Ag HBs – 29 pacienți dintre care 4 ieșiți din tratament; B + C – 4 cu 0 nonresponderi; B + D – 5 cu 2 nonresponderi; B + C + D – niciun caz.

În ***anul 2010***, au fost înregistrate 62 cazuri de HVB, 51 pacienți de sex masculin şi 11 feminin (raportul M/F = 4,63).

În acelaşi an, au fost asistate 297 cazuri, 115 bărbați şi 182 femei (raportul M/F = 0,63), 121 (40,7%) au ieşit din tratament, iar dintre aceştia, 69 (23,2%) au fost consideraţi nonresponderi. Pentru un pacient, schema terapeutică a inclus şi Adefovir.

Pentru întreaga perioadă studiată, 204 (18,1%) au fost pacienți nonresponderi.

CONCLUZII

În perioada 2007-2010, în județul Bacău, au fost asistați terapeutic 1127 pacienți cu hepatite virale cronice cu virus B şi C. Dintre aceştia, 154 (13,7%) au fost cu virus B, iar 973 (86,3%) cu HVC, cu predominanța bărbaților pentru HVB şi cu diferență puternic semnificativă statistic ($p< 0,005$) pentru femeile cu HVC.

Morbiditatea a evidențiat o tendință crescătoare pentru ambele hepatite (B şi C), pentru întreaga perioadă de studiu, fapt explicat prin menținerea în tratament a pacienților în supraveghere, la care s-au adăugat cazurile noi. Acest fapt va conduce la creşterea costurilor asociate cu scăderea calității vieții.

DIAGNOSTIC APPROACHES IN INFECTIVE ENDOCARDITIS

Isabela Ioana Begezsán (Loghin)[1], Carmen Mihaela Dorobăț[2]
1. PhD student at University of Medicine and Pharmacy "Grigore T. Popa" - Iasi
University of Medicine and Pharmacy "Grigore T. Popa" - Iasi

DIAGNOSTIC APPROACHES IN INFECTIVE ENDOCARDITIS (Abstract): Infective endocarditis is a true systemic infection and a life-threatening disease associated with high mortality. **Aim**: To evaluate the problems that occur during making the diagnosis of infective endocarditis, in order to highlight the need of other diagnostic prospects. **Material and methods**: Retrospective study using clinical, microbiological, and echocardiographic findings from 45 patients admitted to the Iasi Infectious Diseases Hospital in the interval January 2007 - January 2011. **Results**: A positive diagnosis of infective endocarditis was made based on Duke Criteria. Inflammatory syndrome revealed leukocytosis with neutrophilia in 42% of the patients. In 91% of the cases fever syndrome was present. Blood cultures were positive in almost 45% of the cases, and the identified etiologic agents were *Staphylococcus spp.*, *Streptococcus spp.*, *Achromobacter spp.*, *Klebsiella spp.*, *Enterococcus spp.*, *E.coli*. In 95% of the patients, the echocardiographic appearance was a major criterion for diagnosis. Associated diseases were most often present with rebound on the course. Cardiac complications occurred despite treatment and re-evaluations. Ten percent of our cases required transfer to cardiology and cardiac surgery units. **Conclusions**: Microbiologic diagnosis was mainly based on cultured-dependent methods that often fail because of previous antibiotic therapy or the involvement of fastidious microorganism. In this case, advances in molecular diagnostics have yielded new tools (polymerase chain reaction - PCR techniques) to diagnose this disease. **Key words**: ENDOCARDITIS, DUKE CRITERIA, BLOOD CULTURE, ECHOCARDIOGRAPHY, PCR.

Infective endocarditis is a life threatening disease associated with high mortality, its sudden or insidious onset causing heart damages, or aggravates a preexisting one which as the disease progresses may affect other organs (1). Although the primary focus of the infection is confined to the endocardium, microbial shedding by continuous bacteremia and embolization of vegetation fragments makes infective endocarditis a true systemic infection. This particular form of systemic infection with unlimited development still has a great impact on the adult population, but not only (2).

While developments in cardiac imaging, therapeutics and surgical techniques have led to improved outcomes in individual patients, the overall incidence has remained relatively stable from the 1950`s through 2000, about 3.7 to 10 cases per 100,000 patient/year (3). The predisposing risk factors have changed over time with intravenous drug abuse, intravascular prosthe-

ses, nosocomial exposure, hemodialysis, and age-related valvular sclerosis being now more prevalent than rheumatic heart disease, especially in the developed countries (4). In addition to these risk factors, studies show that the causative flora implicated in infective endocarditis has also evolved, with *Staphylococcus aureus* emerging as the predominant pathogen, while a recent population-based study disputes this (5).

According to current guidelines, infective endocarditis is diagnosed if microbiological infection of the endocardium is demonstrated. The standard procedure includes clinical and echocardiographic findings plus identification of the causative pathogen (6). In unclear cases, diagnosis may be based on Duke criteria (7). Identification of the causative microorganism is crucial, not only for a proper diagnosis, but also for appropriate antibiotic treatment and management decision, e.g. surgery during active infective endocarditis. Blood cultures are accepted as the gold standard for pathogen identification and quantitative susceptibility testing.

However, in up to 31% of suspected infective endocarditis cases (8, 9), blood cultures remain negative due to previous antibiotic treatment, slow-growing, fastidious, or difficult-to-culture organisms (10), or small amounts of microorganisms per volume. According to the most recent studies, the patients with culture-negative endocarditis, often associated with more complicated courses, may benefit from pathogen identification by polymerase chain reaction (PCR) techniques (6, 11).

MATERIAL AND METHODS

We performed a retrospective study using clinical, microbiological, and echocardiographic findings from 45 patients admitted to the Iasi Infectious Diseases Hospital Iasi between January 2007 and January 2011.

A positive diagnosis of infective endocarditis was based on the clinical picture and laboratory findings according to Durack/Duke diagnosis and classification criteria of infective endocarditis (two major criteria, one major criterion and 3 minor criteria, or 5 minor criteria).

The clinical diagnosis relied on the concurrent presence of major criteria (positive blood cultures, damaged valve at echocardiography, a new heart murmur, worsening or changing the character of existing murmur, though not a sufficient criterion) and minor criteria (predisposing factors: cardiac, intravenous addiction, fever; vascular events: emboli, aneurysm, fungal, intracranial hemorrhages, septic pulmonary infarction, Janeway lesions; immunological manifestations of glomerulonephritis, Osler nodes, Roth spots, presence of rheumatoid factor; suggestive but not conclusive echocardiographic images to be considered a major criterion; also microbiological data: positive blood culture, serological evidence of acute infection with a germ possibly implicated in the etiology of infective endocarditis, splenomegaly, elevated ESR, increased CRP, presence of venous catheters, microscopic hematuria).

The bacteriological diagnosis revealed the causative agent in blood cultures (three samples), and transthoracic and/or transesophageal echo-cardiography in dynamics allowed the identification of certain valvular changes.

RESULTS AND DISCUSSION

Between January 2007 and January 2011, 45 patients with the diagnosis of infective endocarditis were hospitalized at the Iasi Infectious Diseases Hospital.

The yearly distribution of our infective endocarditis cases during the study interval was: most cases were recorded in 2010 (15 cases), followed by 2009, with 11 cases, 2007 and 2008 with 9 cases each, and 1 case in January 2011.

The patients were aged 9 to 76 years, most cases belonging to 40-66 years age group (36 cases); the mean age was 49 years. The patients were prevalently males (35 cases), and residing in urban areas (38 cases).

A positive diagnosis of infective endocarditis was made according to Duke Criteria. Inflammatory syndrome revealed leukocytosis with neutrophilia in 42% of patients. All clinical signs and symptoms specific for infective endocarditis were present in our patients. All patients (45 cases) presented cardiac murmurs, and the most severe symptom was physical and mental fatigue. In 41 (91%) of them fever syndrome was present (fig. 1).

Blood cultures were positive in 20 (44.5%) of the cases. Table I lists the identified etiologic agents: *Staphylococcus spp.*, *Streptococcus spp.*, *E.coli*, *Enterococcus spp.*, *Achromobacter spp.*, *Klebsiella spp.* Blood cultures remained negative in 25 (55.5%) of the cases.

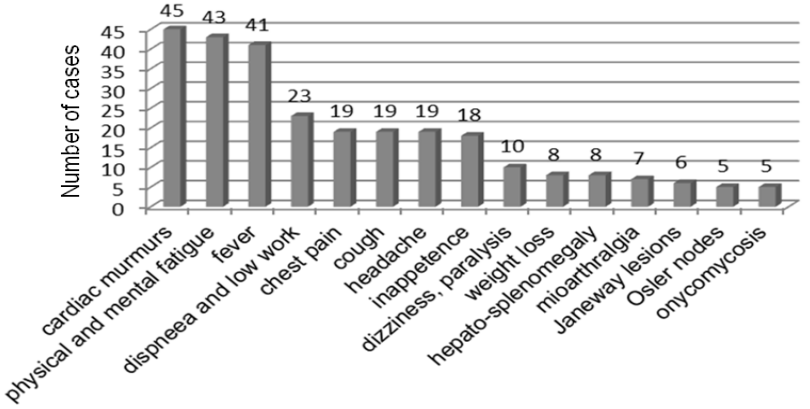

Fig. 1. Clinical signs and symptoms

TABLE I

Distribution of positive blood cultures with the identified etiologic agents, and negative blood cultures

Blood culture	Cases	
	Number	Percentage
Positive blood cultures	20	44.5
Staphylococcus aureus	7	15.5
Streptococcus spp.	4	8.8
Escherichia coli	3	6.6
Enterococcus faecalis	3	6.6
Achromobacter specialis	2	4.4
Klebsiella ozaenae	1	2.2
Negative blood cultures	25	55.5

For a complete diagnosis, transthoracic echocardiography was performed and the echocardiographic appearance was a major criterion for diagnosis. Vegetations were present in 95% of cases on different valves, while a normal appearance could be seen in few cases (4,2%), (fig. 2).

Echocardiographically, the cardiac vegetations were different in size and character (fig. 3).

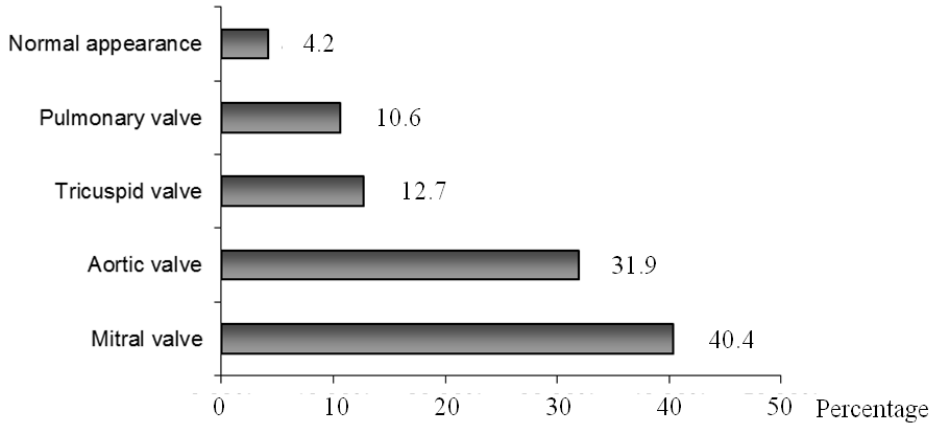

Fig. 2. Echocardiographic distribution of vegetations

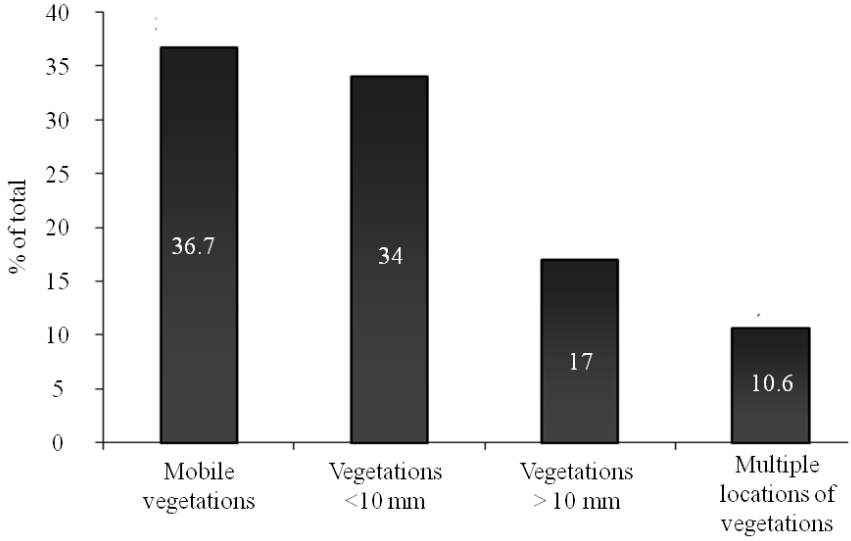

Fig. 3. Echocardiographic character of vegetations

Associated diseases were most often present and had rebound on the course. In most cases, anemia was the severe associated pathology (Table II). Cardiac complications, especially heart failure, occurred despite treatment and re-evaluations (Table III). Ten percent of cases required transfer to cardiology and cardiac surgery units.

TABLE II
Distribution of associated diseases

Associated pathology	Cases	
	Number	Percentage
Anemia	37	82.2
Global chronic heart failure	24	53.3
Mitral insufficiency	17	37.7
Aortic insufficiency	15	33.3
Chronic active hepatitis virus B +D, C	9	20
Arterial hypertension	8	17.7
Tricuspid insufficiency	7	15.5
Aortic stenosis	5	11.1
Severe pulmonary hypertension	5	11.1
Functional acute renal failure	5	11.1
Chronic renal failure	4	8.8

TABLE III
Distribution of complications

Complications	Cases	
	Number	Percentage
Cardiac failure	24	53.3
Pericarditis	6	13.3
Thromboembolism	5	11.1

CONCLUSIONS

Infective endocarditis being a very serious condition it is important to make a quick and appropriate diagnostic, so that the specific treatment to be initiated in time for patients.

A problem appears when blood cultures remain negative, and for finding the etiologic agent a better method than blood culture is needed. The pathogens identified in this study are in the spectrum of the literature reports. The predominant etiologic agent found in the present study was *Staphylococcus aureus*.

Of particular importance was diagnostic imaging by echocardiographic appearance which was a major diagnostic criterion.

Cardiac symptoms dominated the clinical picture. The complexity of associated pathology caused insidious developments.

The microbiologic diagnosis was mainly based on cultured-dependent methods that often fail because of previous antibiotic therapy or the involvement of fastidious microorganism. In this case, advances in molecular diagnostics have yielded new tools to diagnose this disease. Patients with culture-negative endocarditis may benefit today from identification of pathogens by polymerase chain reaction (PCR) techniques.

NOUTĂȚI

DETECȚIA ADN BACTERIAN FOLOSIND NANOPARTICULE DE AUR

Metodele PCR utilizate în diagnosticul bolilor infecțioase necesită personal special instruit şi reactivi foarte costisitori. Padmavathy B şi colab. au explorat posibilitatea folosirii nanoparticulelor de aur (AuNPs) pentru detecția ADN bacterian din probe, printr-un procedeu mai ieftin şi mai uşor de realizat. Au fost elaborate protocoale pentru detecțiia sensibilă şi specifică a tulpinilor de *E. coli* folosind sonde oligonucleotidice cuplate cu nanoparticule de aur (AuNP- oligo probe) care hibridizează cu ADN-ul țintă din probele analizate. Detecția rapidă şi directă a genomului bacterian este posibilă printr-un viraj de culoare, observabil cu ochiul liber, datorită agregării sondelor. Metoda nu necesită amplificarea ADN, are o durată mai mică de 30 de minute după extracția ADN şi o limită de detecție de ~54 ng pentru ADN-ul neamplificat. (Padmavathy B, Vinoth Kumar R, Jaffar Ali BM. A direct detection of *Escherichia coli* genomic DNA using gold nanoprobes. *J Nanobiotechnol* 2012;10(1):8).

CARDIOVASCULAR AND METABOLIC COMORBIDITIES - THERAPEUTIC DIFFICULTIES. CASE REPORT (Abstract): Cardiorespiratory arrest is still a major emergency with a disappointing success rate despite the experts' efforts and the advanced equipment available nowadays. Most cases occur outside the hospital, the experience of resuscitation teams being essential in minimizing long-term neurological sequelae. We report the case of a 67-years-old female patient, old hypertensive, with coronary disease, diabetic, with multiple macro and microvascular complications of diabetes, who was hospitalized for the investigation of a home resurrected cardiorespiratory arrest, with multifactorial etiology. **Keywords:** DIABETES MELLITUS, CARDIORESPIRATORY ARREST, STROKE, ARTERIAL HYPERTENSION.

There are several factors that lead to the cardiorespiratory arrest. The chances of survival of a patient in the cardiopulmonary arrest decrease with time (1). It is extremely important for patients in the cardiorespiratory arrest to receive treatment as quickly as possible regardless of the circumstances in which the arrest occurred and the available resources (2, 3).

Atherosclerotic cardiovascular disease is the leading cause of death in industrialized countries (4). Longevity and number of co-morbidities increased (5). The rate of stroke increases with age, doubling for both men and women after the age of 65 (6, 7). Studies have shown that atrial fibrillation is associated with a 4 to 5-fold increase in ischemic stroke risk, independent of the presence of valvular heart disease. The choice of therapy for the prevention of stroke in patients with atrial fibrillation depends on several factors, including the risk of stroke, the risk of bleeding during anticoagulation therapy and the preference or availability of the patient (8, 9).

Judicious anamnesis and a rigorous, objective, complex and complete clinical examination are very valuable. Proper risk stratification allows prompt and efficient management with significant predictive implications. During the diagnosis, the degree of risk must be constantly re-evaluated.

The therapeutic scheme is guided by patient's co-morbidities. Guidance notes must be followed but apply individually (10).

CASE REPORT

We present the case of a 67-year-old female patient, from rural area, old hypertensive **(**BP max= 170/90 mmHg)**,** diabetic since age of 49 (about 6 months insulin treated), with medical history of acute lower myocardial infarction at age of 65 treated by percutaneous transluminal coronary angioplasty with stent on the anterior descending artery (coronarography at that time revealing tricoronary lesions), dyslipidemia, paroxysmal atrial fibrillation episode at the age of 66 converted with Amiodarone with the initiation of oral anticoagulant treatment with Acenocumarol, an episode of upper digestive hemorrhage manifested by melena 2 weeks before admission (by oral anticoagulation overdose), digestive endoscopy performed after hemodynamic stabilization showing aspect of gastritis and duodenitis, but with the absence of freshly digested blood or lesions with hemorrhagic potential), with acute post-hemorrhagic anemia, who is urgently hospitalized after resuscitation at home, with prompt response to resuscitation maneuvers.

Post-resuscitation, during hospital transportation, the patient develops bradypsychia, bradylalia, right hemiparesis (MRC = 4/5) and generalized contractions. The native cranio-cerebral computed tomography exam performed approximately 40 minutes after the cardiorespiratory arrest occurred showed signs of chronic ischemic stroke in left front-parietal lobe and the right caudate nucleus without the detection of acute ischemic lesions. Also described is diffuse cortical/subcortical atrophy, right putamen calcification and bilateral carotid calcifications.

The objective examination reveals an influenced general state, afebrile, conscious, bradypsychia, difficult cooperation through patents of systemic atherosclerosis, norm ponderal (BMI = 22.4 kg/m^2), stigmata of atherosclerosis – gerontoxon (fig. 1a.) mucocutaneous pallor, dehydrated skin, malar telangiectasias, trophic limb disorders, inferior limb onychodystrophies, left foot ulceration with hematic crust localized in the calcaneal region, imprecisely delimitated with irregular contours and loss of substance, approximately 4/3cm long, and painful edges (fig. 1b.); in the left elbow region of the there is a 5/6 cm nodular swelling area with medium to large hardness, slightly mobile on the deep plane with the presence of Celsius signs (fig. 1c.); SpO_2 = 98% in ambient air, quasi-continuous dyspnea, apexian shock in VIIth intercostal left ventricle on the anterior axillary line, TA = 130/70 mmHg, AV = 72 bpm, rhythmic cardiac noises, III/VI aortic systolic with irradiation on both carotid arteries, mitral systolic murmur grade III/VI with axial irradiation, liver at 2 cm under the rib cage, low pulsatile arteries (left <right), quasi-immobilization in bed (motions only in the bed plan).

An ECG examination was performed at admission with the following findings: sinus rhythm, QRS = 90°, AV = 60 / min, T negative in DI, aVL, QS DIII, T negative V_5-V_6, ST elevation sketch in V1-V4.

The biological investigations revealed mild leukocytosis, normocytic hypochromic anemia, hyperglycemia, nitrate retention syndrome and nonspecific inflammatory syndrome.

Chest radiography reveals cardiomegaly –cardiothoracic index> 0,5, a long elongated left inferior arch, calcification of aortic knob; lung aspect without evolutionary lesions (fig. 2).

a. **b.** **c.**

Fig. 1. Patient assessment highlights

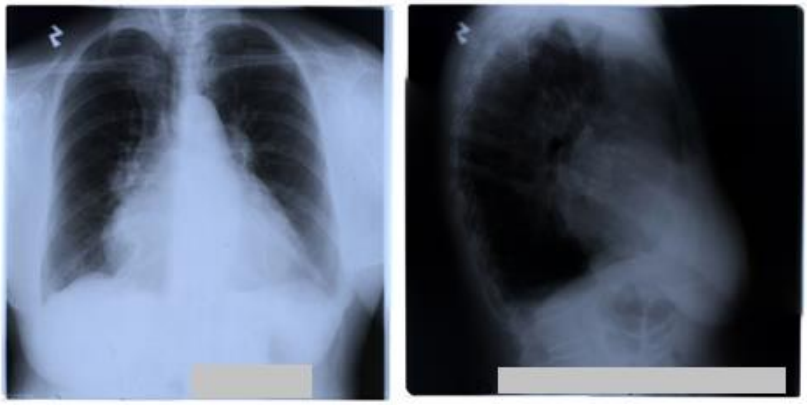

Fig. 2. Chest X-ray

Abdominal ultrasound described liver steatosis, folded gallbladder with calculus (several stones of 5-6 mm), hypoechogenic lipomatosis pancreas, small dimensions of the kidneys (right kidney = 104 mm, parenchymatous index = 7-14mm, 2 mm mean calcification in a dilute calyx, left kidney = 92 mm, parenchymatous index= 11 mm); uterus surgically extirpated; otherwise, abdominal ultrasound does not describe other changes.

Echocardiography reveals cardiomegaly, biatrial dilatation and degenerative mitral valvular changes (mitral ring fibrosis) and aortic (aortic valve sclerosis) with delayed relaxation diastolic dysfunction, EF = 40%, FS = 20% (fig. 3).

Due to the presence of the nodular formation in the left elbow region, a soft ultrasound was performed which found in the subcutaneous tissue a non-homogeneous, imprecisely defined collection, with maximum dimensions 8/17/33 mm, with no Doppler signal inside and in the periphery; and a diffuse infiltrate appearance of adjacent subcutaneous tissue without signs of thrombosis of neighboring vessels.

Vascular surgery consult established the diagnostic of superficial phlebitis located in the inferior third of the upper left limb. Also, the presence of the ulcerative lesion at the left calcaneal region required an eco-Doppler investigation that revealed medio calcinosis in the left femoral artery and in the bilateral popliteal arteries, severe stenosis in the left popliteal artery (90%), with the recommendation of establishing a conservative treatment.

Fig. 3. Echocardiographic changes

It was also determined that the ankle-brachial index that showed the presence of middle obstruction on the right (0.61) and severe on the left (0.4).

We established a general treatment with antibiotic treatment associated with coronary vasodilators, antihypertensive treatment, hypolipidemic, monotherapy antiplatelet drugs, gastro protector, antiarrhythmic, diuretic, martial and topical therapy has been instituted.

Clinical evolution was slowly favorable with progressive improvement in dyspnea, tendency to epithelialization of the plantar ulcer, and remission of inflammatory phenomena from the left elbow, but eluded by neurological complications and diabetes by plurivascular affection, with increased bradylalia and bradypsychia, and evolution to mixed aphasia.

DISCUSSION

Major cardiovascular events at hypertensive patients are preceded by the development of structural and functional cardiovascular and renal abnormalities, most of which are recognized as significant independent predictors of subsequent cardiovascular complications (11).

People with type 2 diabetes have a 1.54 to 4 times higher risk of developing a coronary disease, with a younger onset with a higher severity of the lesion and a lower prognosis, compared to individuals without diabetes. Studies have also shown that cerebrovascular disease morbidity is 2-5 times higher in type 2 diabetic patients than in non-diabetic individuals (4). In the general population, women show a delay of about 10 years compared to men, regarding the occurrence of subclinical atherosclerosis and cardiovascular events (12).

The recommendations of the American College of Chest Physicians (ACCP) guidelines for atrial fibrillation are as follows:

- Warfarin is routed to all high-risk patients and to all patients over 75 years of age, regardless of their risk;
- Low-risk patients and patients under 65 years of age should be treated with aspirin;
- Patients aged 65-75 without risk factors will receive oral anticoagulant treatment based on associated comorbidities (9).

The prognosis of this case is reserved both in the short term for the possibility of occurrence of immediate thromboembolic complications with vital and long-term risk

through coronary complications (patient with tricoronary lesions), rhythm and/or conduction disorders, hemorrhagic transformation of chronic stroke from the territory front-parietal left, complications secondary to diabetes. Also, the prolonged decubitus caused by the right hemiparesis causes trophic and tissue complications.

CONCLUSIONS

Caring for patients with multiple comorbidities requires knowledge of both the manifestations caused by the pathology involved, and especially the difficult issues within the therapeutic plan. Individualized therapeutic regimens, flexibility and empathy towards the wishes of each patient, providing psychological and emotional comfort that motivates them to constantly care for their health, are just a few principles that underlie therapeutic monitoring. In this context, a multidisciplinary therapeutic approach, medical teamwork, collaboration with the family doctor and other specialties is needed that manages the evolution of the patient's general pathology.

3. Disciplina de Farmacologie

THE EFFECTS OF ETHANOL ON THE EVOLUTION OF THE ACUTE BENZODIAZEPINE POISONING (Abstract): The depressing effects on the nervous central system (NCS) induced by benzodiazepines and ethanol are similar. The complications are rare in the benzodiazepine poisoning, but are a lot more frequent in association with other depressing drugs for the NCS (especially alcohol). **Material and methods:** We analyzed retrospectively patients with benzodiazepine poisoning admitted in the Internal Medicine Clinic – Toxicology during 2003 – 2009.The study attempted a complex evaluation of the consequences of acute and chronic alcoholism on the evolution of acute benzodiazepinepoisoning and the description of the clinic evolution and paraclinical particularities of the patients under investigation. **Results:** 343 patients with benzodiazepine poisoning were admitted, 150 were tested through measurement of alcohol level, leading to values between 1 – 415 mg/dl. Chronic alcoholism in personal pathological antecedents of the patients determined a relative risk of intoxication 1.46 times higher. The hospitalization period varied from 1 to 8 days for patients with chronic alcoholism and from 1 to 14 days for patients with acute alcoholism, a statistically important difference. **Conclusions:** During the period under investigation, from the total of patients admitted for acute benzodiazepine poisoning, 2 deaths were registered. Of the two deaths, one patient showed ethanol coingestion. **Key words:** BENZODIAZEPINE POISONING, CHRONIC ALCOHOLISM, ACUTE ALCOHOLISM.

Intoxicaţiile acute cu benzodiazepine (BZD) constituie o cauză importantă de morbiditate şi mortalitate în întreaga lume. Cel mai adesea, intoxicaţiile survin la pacienţi etilici cronici sau pe fond de etilism acut,ceea ce face ca managementul lor să devină extrem de dificil.

BZD administrate în doze peste limita terapeutică produc doar semne minime şi moderate de toxicitate, incluzând ataxie, dizartrie şi letargie, dar dozele foarte mari pot cauza comă, hipotensiune, hipotermie şi depresie respiratorie, necesitând intubaţie oro-traheală şi ventilaţie asistată (1, 2).

În intoxicaţiile cu benzodiazepine complicatiile sunt rareori semnalate, dar sunt mult mai frecvente în asociere cu alte droguri deprimante ale sistemului nervos central (SNC), în special alcoolul.

Depresia SNC este mai accentuată la vârstnici, la pacienţi cu boli cronice (ciroză, hepatopatii) şi la pacienţi în tratament cu medicaţie ce interferă cu metabolismul hepatic al BZD: macrolide (claritromicina,

eritromicina), blocante calcice (verapamil, diltiazem), antifungice (fluconazol, ketoconazol), antidepresive (fluoxetin), inhibitori de pompă protonică (omeprazol). De asemenea, coingestia de suc de grapefruit şi de alcool poate creşte concentraţia serică de BZD (3, 4, 5, 6).

Efectele deprimante asupra SNC induse de BZD şi etanol sunt similare. Alcoolul acţionează asupra complexului funcţional format de acidul gamma-aminobutiric (GABA), receptorul pentru BZD şi canale de clor, crescând afinitatea de legare a BZD la situsul BZD, având efect aditiv şi de potenţare a efectului deprimant SNC şi la nivelul aparatului respirator (2,8,9,10).

Lucrarea urmăreşte evaluarea complexă a consecinţelor etilismului acut şi cronic asupra evoluţiei intoxicaţiilor acute cu BZD si descrierea particularităţilor clinico-evolutive şi paraclinice ale pacienţilor incluşi in studiu.

MATERIAL ŞI METODE

Cercetările au inclus 343 pacienţi intoxicaţi cu BZD, asistaţi în Clinica Medicală –Toxicologie şi ATI a Spitalul Clinic de Urgenţe Iaşi, în perioada 2003-2009. Pe baza investigaţiilor clinice şi paraclinice, s-a încercat evidenţierea influenţei etilismului cronic sau acut, ca factor de risc, asupra stării de sănătate a populaţiei. Culegerea datelor s-a realizat prin investigaţii clinice şi paraclinice, analiza foilor de observaţie şi ancheta clinico-epidemiologica. Pentru prelucrarea şi interpretarea datelor obţinute s-au folosit metode epidemiologice, de laborator şi statistico-matematice.

REZULTATE SI DISCUTII

1. Evaluarea nivelului alcoolemiei la pacienţii intoxicaţi cu benzodiazepine.

Din numărul total de pacienţi intoxicaţi cu BZD, 43,7% dintre pacienţi au fost testaţi prin măsurarea alcoolemiei, obţinându-se valori de la 1 la 415 mg/dl. (fig. 1).

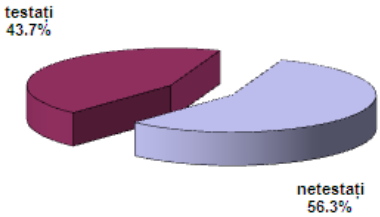

Fig. 1. Distribuţia pacienţilor intoxicaţi cu benzodiazepine în relaţie cu investigarea alcoolemiei

Valorile normale ale alcoolemiei, indicate de Laboratorul de Biochimie a Spitalului de Urgenţă „Sf. Ioan" Iaşi, se află în intervalul 1-10 mg/dl, iar cele înregistrate peste această limită la pacienţii testaţi la internare au variat de la 11 la peste 300mg/dl (tab. I, fig. 2).

2. Analiza în relaţie cu sexul pacienţilor cu etilism peste limita normală,a remarcat căponderea pacienţilor de sex masculin (29/56) cu valori peste limita admisă nu a prezentat diferenţe semnificative faţă de cea a pacienţilor de sex feminin (51/94) (χ^2=0,02; GL=1, p=0,901) (fig. 3).

Valorile medii ale alcoolemiei, înregistrate la pacienţii de sex feminin au fost semnificativ mai scăzute (74,16±9,84 $g^o/_{oo}$) decât la cei de sex masculin (87,70±11,54 $g^o/_{oo}$) (t=7,33; GL=148; p<0,001).

TABELUL I

Nivelul alcoolemiei la pacienţii intoxicaţi cu benzodiazepine

Alcoolemie (mg/dl)	% din totalul pacienţilor testaţi
11-100	14,5
101-200	17,7
201-300	12,9
>300	9,7

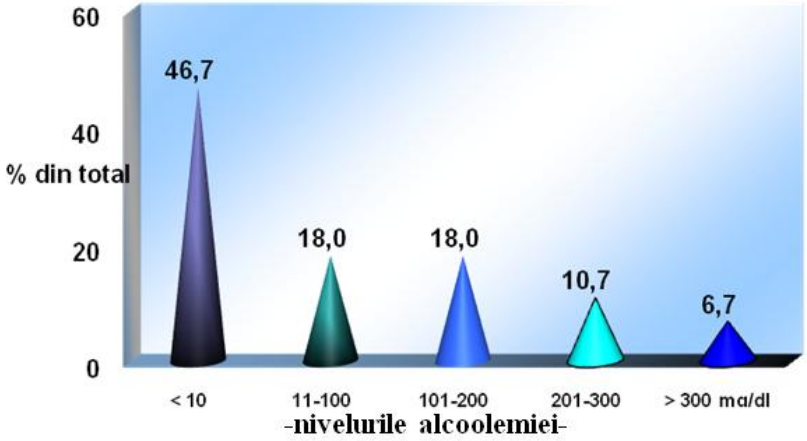

Fig. 2. Distribuția pacienților intoxicați cu benzodiazepine în relație cu nivelul alcoolemiei înregistrat la internare

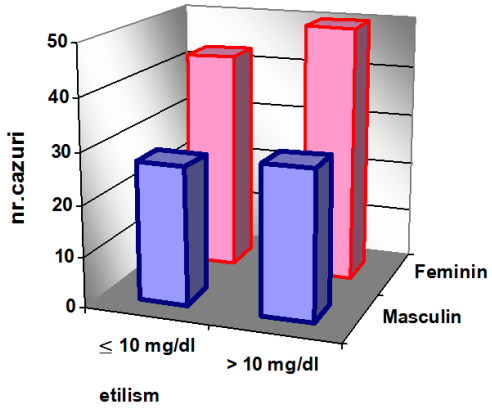

Fig. 3. Distribuția pe sexe a pacienților intoxicați cu benzodiazepine în relație cu nivelul alcoolemiei înregistrat la internare

3. Analiza cazurilor în relație cu mediul de proveniență.

A rezultat că ponderea cazurilor provenite din mediul urban cu alcoolemie peste limita normală din total testați (60/98) a fost semnificativ mai crescută comparativ cu cele din mediul rural (20/52) (χ^2=6,19; GL=1; p=0,013); riscul relativ de intoxicație cu benzodiazepine a fost de 1,59 ori mai mare la pacienții din urban cu coingestie de alcool (RR=1,59; IC95%: 1,09÷2,32) (fig. 4).

Valorile medii ale alcoolemiei, înregistrate la pacienții proveniți din mediul urban (106,45±90,61 $g^o/_{oo}$) nu au fost semnificativ mai crescute decât la cei din mediul rural (93,39±57,33 $g^o/_{oo}$) (t=1,08; GL=148; p>0,05).

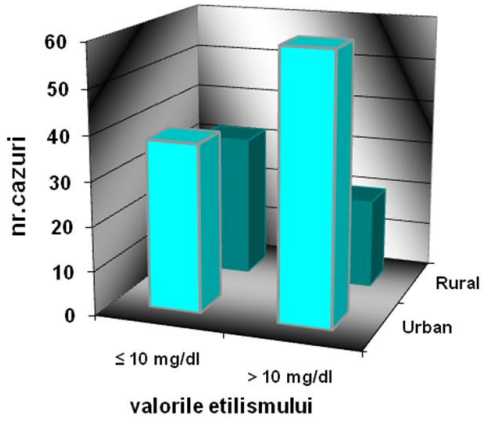

Fig. 4. Distribuția pacienților testați în relație cu nivelul alcoolemiei înregistrat la internare și mediul de proveniență

4. Evaluări privind prevalența cazurilor de etilism şi durata de spitalizare

Anamneza pacienților cu coingestie de alcool din lotul studiat a identificat existența a 46,7% cazuri cu etilism acut, iar ponderea celor cu etilism cronic, cu valori la internare ale concentrației de alcool peste limita normală (32/47) a fost semnificativ mai mare față de cazurile cu etilism acut (48/103) (p=0,023). Etilismul cronic în antecedentele patologice personale ale pacienților a determinat un risc relativ de 1,46 ori mai mare de intoxicație (RR=1,46; IC95%: 1,10÷1,94) (fig. 5, 6).

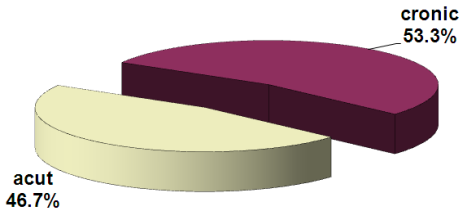

Fig. 5. Distribuția pacienților cu coingestie de alcool în relație cu tipul de etilism

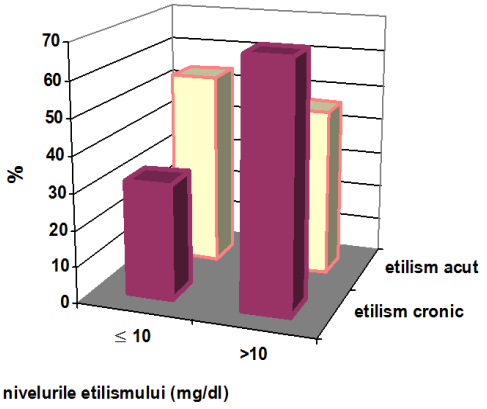

Fig. 6. Distribuția pacienților intoxicați cu benzodiazepine în relație cu nivelul alcoolemiei înregistrat la internare şi antecedentele patologice personale

Pacienții cu intoxicații cu benzodiazepine şi coingestie de alcool au înregistrat o perioadă de spitalizare care a variat de la 1 la 8 zile pentru cei cu etilism cronic şi de la 1 la 14 zile în cazul etilismului acut.

În relație cu prezența etilismului acut la pacienții intoxicați cu BZD, valorile medii ale perioadei de spitalizare au fost semnificativ mai crescute (t=3,13; GL=148; p<0,002) (fig. 7).

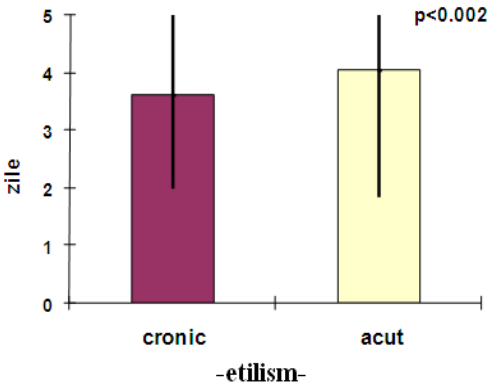

Fig. 7. Valorile medii ale perioadei de spitalizare la pacienții intoxicați cu benzodiazepine în relație cu tipurile de etilism

În perioada studiată,din totalul pacienților spitalizați pentru intoxicație acută cu BZD s-au înregistrat 2 decese, din care numai un pacient a fost cu etilism acut, diferență nesemnificativă din punct de vedere statistic (p=0,936).

CONCLUZII

Ponderea pacienților de sex masculin (29/56) cu valori peste limita admisă a alcoolemiei nu a prezentat diferențe semnificative comparativ cu cei de sex feminin (51/94) (χ^2=0,02; GL=1, p=0,901).

Etilismul cronic în antecedentele pato-

logice personale ale pacienților a determinat un risc relativ de intoxicație de 1,46 ori mai mare.

Perioada de spitalizare a variat de la 1 la 8 zile la pacienții cu etilism cronic şi de la 1 la 14 zile la cei cu etilism acut, diferența fiind semnificativă statistic.

Din totalul pacienților spitalizați pentru intoxicație acută cu BZD s-au înregistrat 2 decese, dintre care unul la un pacient spitalizat cu etilism acut, cu o diferență statistică nesemnificativă (p=0,936).

CHARACTERISTICS OF HEPATITIS C VIRUS (HCV) INFECTION IN CLOSED COMMUNITIES (Abstract). **Aim:** To determine the prevalence of HCV in closed communities and the relations between risk behavior and HCV infection. **Material and methods**: The persons deprived of personal freedom selected for this study have filled out an epidemiological questionnaire including identity and epidemiological data (detention history, evaluation of the risk factors), as well as a written consent. All the subjects were tested for the presence of anti-HCV antibodies. **Results**: This study included 326 of the total of 500 persons deprived of personal freedoms at the Bacau Correctional Facility The prevalence of hepatitis B and C was 15.34 %, and that of HCV 5.21%, higher than in the general population. Risk factors associated with HCV in closed communities were injected drugs, homosexuality, and tattooing. **Conclusions**: The results confirm that the population in correctional facilities is at high risk for infection with hepatitis viruses (both B and C), the modes of disease transmission being already known. **Key words**: HEPATITIS C VIRUS, PREVALENCE OF HCV INFECTION, RISK BEHAVIOR, CORRECTIONAL FACILITIES

Prevalenţa VHC la nivel mondial este de 3%, ceea ce corespunde unui număr de aproximativ 170 milioane persoane (1). Această estimare este realizată cel mai frecvent pe baza ratei prevalenţei în rândul donatorilor de sânge, ceea ce face ca numărul real să fie subestimat.

Până în prezent s-au identificat şase genotipuri (notate de la 1 la 6) şi mai multe subtipuri ale VHC, a căror răspândire şi răspuns la tratament sunt diferite (2). Pentru România valorile prevalenţei sunt cuprinse între 1,8-9,6% (3).

OMS estimează că la nivel mondial se înregistrează mai mult de 1,1 milioane decese legate de infecţia cu VHC (care, ca număr de persoane, este de patru ori mai frecventă ca HIV) (4).

Principala cale de transmitere a infecţiei cu VHC este cea sanguină, putându-se realiza în două moduri: direct (de ex. prin transfuzii de sânge) sau indirect (de ex. prin administrarea intravenoasă de droguri, urmare a partajării echipamentului de injectare, această cale fiind considerată principalul factor de risc în ţările dezvoltate). Au fost identificate următoarele căi posibile: utilizarea drogurilor intravenos; transplantul de organe; contactul sexual (cu un IDU – injection drug user); detenţia mai mare de trei zile; scarificarea religioasă; heteroagresiuni/agresiuni cu un obiect contaminat cu

sânge sau alte fluide biologice infectate; piercing, tatuaj, acupunctură; infecţii în instituţii sanitare (ocupaţionale şi nosocomiale) (1,2,5-7).

Utilizarea drogurilor injectabile a devenit cea mai frecventă formă de transmitere a VHC. Majoritatea infecţiilor nou dobândite apare la indivizii care îşi injectează sau şi-au injectat droguri ilicite. Seroprevalenţa anticorpilor anti VHC în grupul IDU poate ajunge la 80-90% (8), având variaţii ce ţin de regiune, comportament la risc, status socio-economic, etc. Infecţia VHC este asociată şi cu antecedentele de utilizare intranazală (prizare) a cocainei (alcalină şi corozivă), datorită prezenţei sângelui pe dispozitivele de prizare şi partajării acestora (9,10). Statusul de VHC în rândul IDU este asociat cu: partajarea seringilor şi a echipamentului de injectare; numărul de ani de injectare; frecvenţa injectării; vârsta; nivelul consumului de drog; coinfecţia cu VHB; consumul excesiv de alcool; detenţia; sexul masculin (11,12).

Literatura de specialitate recunoaşte că utilizarea ilicită a drogurilor reprezintă factorul de risc principal şi major în transmiterea VHC (13-18). Consumul de droguri şi detenţia cresc riscul de infecţie VHC. Rata încarcerărilor printre IDU, ca şi proporţia IDU în rândul deţinuţilor sunt mai mari decât în populaţia generală (12). Intrarea într-un sistem penitenciar scade (măcar teoretic) consumul de droguri, dar reprezintă foarte des un prim pas în iniţierea consumului acestor substanţe. Studii citate de K. Dolan (19) arată că deţinuţii din penitenciare cu regim de securitate scăzut au risc mai mare de infecţie datorită posibilităţii injectării de droguri (48%) decât cei din penitenciare de securitate medie (27%) sau maximă (18%). Ca şi în cazul infecţiei cu VHB, la consumul de substanţe ilicite se adaugă şi alţi factori de risc (20): comportament şi activitate sexuală la risc în penitenciare (14,16), istoricul detenţiei (numărul sentinţelor, durata totală a timpului petrecut în închisoare, frecvenţa reîncarcerărilor, tatuarea şi piercing-ul corporal realizate în penitenciar în condiţii improprii şi cu echipamente improvizate (21), leziuni (autorăniri, heteroagresiuni), afecţiuni mentale (22), suprapopularea/supraaglomerarea. Prevalenţa infecţiei virale C în rândurile p.p.l. diferă foarte mult în funcţie de regiune, tipul penitenciarului (gradul de securitate), structura populaţieie penitenciare, prezenţa şi importanţa unor grupuri de risc (19).

Scopul acestui studiu a fost stabilirea prevalenţei infecţiei virale C în colectivităţi închise (penitenciar) şi stabilirea factorilor de risc ai transmiterii VHC în aceste comunităţi.

MATERIAL ŞI METODĂ

În studiu au fost incluşi rezidenţii Penitenciarului Bacău pe o perioadă de 3 ani (2007-2010). După semnarea consimţământului informat, subiecţii au completat un chestionar epidemiologic şi au fost supuşi unui examen clinic general. Chestionarul epidemiologic a cuprins date de identificare şi date epidemiologice (istoricul detenţiei/detenţiilor, evaluarea factorilor de risc: administrare de droguri injectabile, tatuare, hetero/autoagresiuni, partajul obiectelor de toaletă, intervenţii chirurgicale sau stomatologice, călătoria în străinătate şi eventual în zone cu endemicitate crescută). Toţi subiecţii au fost testaţi pentru prezenţa Ag HBs prin metoda ELISA.

Datele statistice au fost prelucrate cu ajutorul programului SPSS 16.0. Am utilizat pentru compararea valorilor testul Chi pătrat, iar valorile neparametrice au fost interpretate cu ajutorul testului Mann-

Whitney de comparare a rangurilor.

REZULTATE

Din totalul de 500 deţinuţi din Penitenciarul Bacău, 326 au semnat consimţământul informat şi doar 141 au completat chestionarul epidemiologic.

Vârsta medie a lotului a fost de 30,94 ± 9,67 ani (femei 32,84 ± 8,92 ani, bărbaţi 30,65 ± 9,77 ani), cu o vârsta medie a subiecţilor cu VHC de 28 ani (95% IC 24,14-31,81). Au fost completate 141 de chestionare (43,25% dintre subiecţii incluşi în studiu). Doar la 197 (60,43%) dintre deţinuţii incluşi în studiu s-au efectuat analize medicale complete. Au existat 31 persoane (22%) pentru care au fost realizate analize medicale complete şi care au acceptat să completeze şi chestionarul, neexistând situaţii de p.p.l. incluse în studiu şi care să nu fi răspuns măcar la unul din cele două forme de investigare folosite. Întregul lot a fost însă testat pentru prezenţa Ac anti VHC (anticorpi anti VHC).

În urma analizelor efectuate s-a obţinut o prevalenţă a Ac anti VHC de 5,21%. Datorită structurii penitenciare din perioada desfăşurării studiului, numărul de cazuri cu Ac anti VHC prezenţi a fost mai mare la p.p.l. de sex masculin de 4,66 ori.

Majoritatea celor incluşi în studiu a făcut parte din grupa de vârstă 20-45 ani, prezenţa Ac anti VHC fiind preponderentă la aceeaşi grupă de vârstă. Pentru a vedea dacă s-au înregistrat diferenţe semnificativ statistice între valorile vârstei pe diferitele categorii de subiecţi incluşi în lotul de studiu, am folosit testele de semnificaţie statistică. Testul de normalitate Kolmogorov – Smirnov a aratat că valorile vârstei nu respectă legea de distribuţie normală (Z = 1,805, p = 0,003), deci pentru a compara aceste valori am folosit doar teste neparametrice. Am folosit testul Mann-Whitney de comparare a rangurilor, care a aratat că nu există diferenţe semnificative statistic între valorile vârstei pe sexe (U = 5200.500, p = 0.084) şi nici între subiecţii pozitiv / negativi pentru anticorpi anti VHC (U = 2172.000, p = 0.229).

Pentru ambele sexe mediul de proveniență a fost preponderent urban. Pentru infecţia virală C mediul rural acţionează ca factor de protecţie, riscul asociat fiind de 0,655, însă nu au existat diferenţe semnificativ statistice între frecvenţa infecţieie virale C în mediul urban faţă de mediul rural (OR 2,15, p=0,457).

Majoritatea subiecţilor era de etnie română (82,45%), dintre aceştia 92,3% având Ac anti VHC prezenţi (OR 1,96, p=0,522).

Nivelul de educaţie nu a influenţat probabilitatea infecţiei VHC. Cei mai mulţi aveau terminate 12 clase (liceul) ca nivel de studii, 7,9% dintre aceştia prezentau Ac anti VHC (p=0,603).

În lotul studiat nivelul socio-economic era mediu spre scăzut, 14,7% dintre şomeri prezentau Ac anti VHC, spre deosebire de doar 3,2% dintre subiecţii angajaţi (p= 0,028).

Cea mai mare frecvenţă a infecţiei virale C a fost înregistrată la persoanele necăsătorite (12,5%) spre deosebire de cele căsătorite, unde frecvenţa a fost de 8,5% (p=0,364). În urma completării chestionarului au fost identificaţi mai mulţi factori de risc asociaţi cu infecţia virală C (tab. I).

În rândul subiecţilor cu relaţii sexuale cu parteneri de acelaşi sex riscul de infecţie virală C este de 9,5 ori mai mare. Utilizarea de droguri intravenoase creşte riscul de infecţie virală C de 8,1 ori.

Prezenţa tatuajelor creşte riscul de infecţie virală C de 2,6 ori, majoritatea tatuajelor la cei infectaţi fiind realizate în penitenciar.

TABEL I

Factori de risc asociaţi cu VHC în colectivităţi închise

Caracteristici	Prevalenţa VHC (%)	OR (95% IC)	RR	p
Călătorii în străinătate	7,4	0,693 (0,203-2,321)	0,716	0.343
Alte condamnări	11,1	1,500 (0,477-4,714)	1,444	0.485
Homosexualitate	33,3	13,750 (3,827-49,398)	9,500	<0.001
Tatuaje	12,7	2,850 (0,749-10,844)	2,161	0.111
Leziuni autoprovocate	13,3	1,744 (0,498-6,110)	1,644	0.380
Consum de droguri intravenoase	60,0	18,900 (2,823-126,558)	8,160	<0.001
Tratamente injectabile la domiciliu	12,2	1,694 (0,536-5,354)	1,609	0.365

DISCUŢII

Infecţia cu VHC recunoaşte drept cale majoră de transmitere calea sanguină. Alte căi importante sunt cea sexuală şi cea verticală (materno-fetală). A doua cale de transmitere nu a făcut obiectul studiului.

Prevalenţa infecţiei virale C în lotul studiat a fost de 5,21%, mai mare faţă de prevalenţa VHC din populaţia generală a României - 3,52% (23).

Structura populaţiei penitenciare a influenţat unele rezultate. Faptul că în perioada desfăşurării studiului, populaţia de sex feminin a penitenciarului era de aproximativ 5% din total a determinat o prevalenţă mai mare a infecţiei VHC în rândul persoanelor de sex masculin. Aceste rezultate sunt în contradicţie cu un studiu (23) efectuat la nivel naţional, în care persoanele de sex feminin aveau o proporţie a infecţiei cu VHC mai mare decât cele de sex masculin (care acţionează ca factor protectiv), infecţia fiind de asemenea mai frecventă în mediul rural (din cauza sanitaţiei, educaţiei şi nivelului socio-economic mai scăzute aici). În studiul nostru însă, dimpotrivă, mediul rural acţionează ca factor de protecţie, pentru cei care provin din acest mediu, existând de 0,655 ori mai puţine şanse de a se infecta cu VHC. Acest fapt este explicat prin mediul de proveniență a deţinuţilor, cei mai mulţi provenind din mediul urban, unde grupurile ce se angajează în activităţi la risc (de ex. consumul de droguri ilicite) sunt mai numeroase, la nivelul penitenciarului aceste grupuri agregându-se şi continuând acelaşi comportament la risc (mediul penitenciar este recunoscut ca fiind un loc propice pentru astfel de activităţi). Atât în studiul sus-amintit (23), cât şi în studiul nostru, nivelul ridicat de educaţie a constituit un factor protector faţă de achiziţionarea infecţiei cu VHC, la fel ca şi statusul marital (căsătoria este un factor protector) şi statusul socio-economic (cei neangajaţi sau neimplicaţi într-o activitate productivă legală au şanse mai mari de a se infecta cu VHC).

Un aspect aparte şi foarte obişnuit printre deţinuţi, indiferent din care sistem penitenciar provin, îl reprezintă tatuarea. Tatuajul este recunoscut ca factor de risc în transmiterea infecţiei cu VHC (20,24). În studiul nostru 82,3% din tatuaje au fost realizate în penitenciar, tatuarea fiind un factor de risc pronunţat pentru infecţia VHC (de 2,616 ori mai multe şanse de infecţie). Deşi nu constituie calea majoră

de transmitere, relaţiile sexuale cu parteneri de acelaşi sex (25) (homosexualitatea temporară - pe perioada detenţiei) reprezintă un factor de risc foarte important, existând de 9,5 ori mai multe şanse de infecţie, leziunile autoprovocate având un risc mediu de infecţie cu VHC.

Corespunzător datelor din literatura de specialitate (11,26) utilizarea substanţelor ilicite reprezintă un risc foarte important pentru infecţia VHC. Dacă se adaugă încă un factor de risc (de ex. tatuarea), riscul creşte exponenţial (9). Importanţa acestei căi de transmitere, încercarea de a înţelege modalităţile de transmitere a VHC la IDU s-au concretizat în numeroase studii (10,27), inclusiv în realizarea de modele matematice ale transmiterii şi ale influenţei utilizării de substanţe legale în achiziţionarea VHC de către IDU (12,28). Numărul de condamnări şi anii petrecuţi în detenţie determină un risc, deşi slab, de a achiziţiona infecţia cu virusurile hepatitice. Aceste argumente sunt în favoarea aserţiunii potrivit căreia detenţia în general (prin modul de viaţă şi comportament pe perioada executării pedepsei) are un rol de seamă în transmiterea infecţiei cu virusuri hepatitice şi în perpetuarea unui important izvor de virus. Rezultatele obţinute de noi contrazic un studiul citat mai înainte (23) potrivit căruia detenţia nu se corelează din punct de vedere epidemiologic cu infecţia VHC.

În studiul efectuat nu am găsit ca fiind factori de risc pentru infecţia cu VHC administrarea de tratamente injectabile la domiciliu, împărţirea obiectelor personale de igienă, accidentele de circulaţie, acupunctura, frecventarea saloanelor de cosmetică/manichiură/pedichiură, intervenţiile chirurgicale sau spitalizările.

Inexistenţa unui vaccin (în momentul de faţă) împotriva VHC face imperios necesară realizarea unei strategii de screening, prevenţie şi tratament (12,27) prin adoptarea unor programe bine elaborate, care să aibă drept ţintă grupurile cu risc major, un astfel de grup constituindu-l deţinuţii.

Datele obţinute susţin necesitatea imperioasă a elaborării unor programe de screening, prevenţie şi tratament în rândul persoanelor instituţionalizate (mai ales din perspectiva absenţei, în momentul actual, al unui vaccin anti VHC), dar şi întreprinderea unor iniţiative legislative care să sprijine astfel de programe.

CONCLUZII

Datele obţinute concordă cu cele din literatură, ele demonstrează că infecţia cu VHC este mai frecventă decât în populaţia generală. Valorile mai mici sunt probabil rezultatul structurii populaţiei carcerale din Penitenciarul Bacău, în momentul realizării studiului. Este posibil ca realizarea unui astfel de studiu în facilităţi corecţionale cu o altă structură a populaţiei să conducă la date mai apropiate de cele din alte ţări.

ECTOPIC ADRENOCORTICOTROPIC HORMONE SYNDROME CAUSED BY A THYMIC CARCINOID. CASE REPORT. (Abstract). Ectopic ACTH secretion accounts for less that 10% of all causes of endogenous Cushing's syndrome. Carcinoids are rare thymic tumors, and when associated with ACTH hypersecretion display local or distant aggressive behavior. A 32-year-old woman was admitted to the Endocrinology Unit for obesity, moon face, facial hirsutism, hyperpigmentation, and secondary amenorrhea. Laboratory test confirmed the hypercortisolism and excess ACTH, while dexamethasone suppressive test was negative. Thorax computed tomography (CT) showed an antero-superior mediastinal tumor invading the pericardium and left mediastinal pleura. A complete resection through median sternotomy of the tumor, pericardium and left mediastinal pleura was performed. After a one-year symptom-free period, hypercortisolism recurred, confirmed by laboratory findings. Although no signs of local recurrence were seen on thorax CT, left internal mammary lymph nodes involvement and vertebral body metastases at C7 and L1 were found. Refractory electrolyte disturbances could not be corrected resulting in severe cardiac arrhythmia and death from cardiac arrest. The reported case draws attention on the aggressiveness of ACTH-secreting thymic carcinoid both oncologically and also due to the refractory electrolyte disturbances with fatal outcome. **Key words:** CARCINOID, THYMUS, ECTOPIC ACTH SECRETION, CUSHING'S SYNDROME

Ectopic ACTH secretion accounts for less than 10% of all causes of endogenous Cushing's syndrome (1,2). Carcinoid tumours are derived from enterochromaffin cells and are classically described as originating from the embryological foregut, midgut or hindgut. Thymic carcinoids are rare thymic tumours, divided into three forms: nonsecretory tumours, hormonal secretory tumours and tumours associated with multiple endocrine neoplasia type 1 (3-5).

CASE REPORT

A 32-year old female patient was admitted in the Endocrinology Unit with typical clinical aspect of hypercortisolism (moon

face, obesity, facial hirsutism, hyperpigmentation, secondary amenorrhea), the onset being noticed three months ago.

The endocrinological work up confirmed the hypercortisolism, as follows:

- plasmatic cortisol was high: 582 ng/mg at 8 am (normal: 50-230 ng/mg) and 590 ng/mg at 11 pm (normal: 30-150 ng/mg);
- urinary cortisol was, also, high: 532 ug/24 h (n 9-180);
- low plasmatic potassium, metabolic alkalosis and hyperglycemia were considered secondary to hypercortisolism;
- ACTH was also elevated (292 pg/ml, n < 46) and, given the negative dexamethasone suppressive test, the diagnosis of Cushing's syndrome was endorsed.

In order to investigate the source of ACTH excess, a radiography of the skull and a magnetic resonance image (MRI) of the head were performed, but no abnormalities were shown. Except polycystic ovaries, ultrasound and computer tomography of the abdomen were normal.

Thorax CT revealed an anterior mediastinal mass of 32/42/49 mm in contact with pericardium and left mediastinal pleura, consistent with a tumor of the thymus (fig. 1).

Fig. 1. Pre-operative thorax CT image. An anterior mediastinal mass of 32/42/49 mm in contact with pericardium and left mediastinal pleura was evident.

The preoperative diagnosis was of an ectopic ACTH secreting thymic tumor. The patient was scheduled for surgery and a medical preoperative treatment consisting of beta-blockers, angiotensin converting enzyme inhibitor, ketoconasole, spironolactone, and oral antidiabetics was commenced.

On July 2008 the patient underwent an extended thymomectomy through a longitudinal complete sternotomy. The tumour was located in the antero-superior mediastinum, invading the pericardium and left mediastinal pleura which were resected en block with the thymic tumour.

Pathology assessment

Macroscopically it was described a 5/4/2 cm tumour, of hard consistency and fatty aspect on cross section. The microscopical examination showed, besides thymic tissue with interstitial sclerosis and calcifications, a malignant proliferation with rare mitoses and foci of necrosis. The tumor exhibited a compact architecture and cellular pleomorphism, with invasion of the extracapsular space and vascular emboli (fig. 2, a) and b). No malignant cells were found in the mediastinal fatty tissue, pericardium and pleura portion removed with the tumor.

The immunohistochemistry (IHC) assessment showed - enolase neuron specific (NSE) was intense positive (fig. 3), chromogranin was positive (fig. 4), synaptophisin was intense positive (fig. 5), - citokeratine cocktail (MNF 116) was moderate positive (fig. 6) and Ki 67 was 10% (fig. 7).

Given the IHC, the final diagnosis was of a carcinoid carcinoma of the thymus with ACTH secretion. The immediate postoperative course was uneventful and the patient was discharged 12 days following surgery. The clinical examination and hormonal assessment at follow-up examination after one month showed the disappearance of the hypercortisolism were: plasma cortisol - 97,4 ng/ml at 8 am and 3,9 ng/ml at 11 pm; urinary cortisol - 178,9 μg/24 h; ACTH 37 pg/ml.

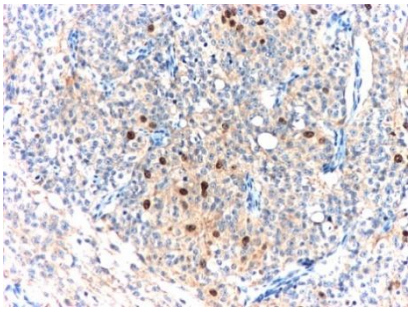

Fig. 7. IHC – Ki 67 10 %

The patient was disease-free for one year following surgery she, but in July 2009 the symptoms of Cushing's syndrome reoccurred, confirmed by the lab tests. The thorax CT scan revealed left internal mammary lymph nodes enlargement and metastases of the body of C7 and L1 vertebrae, confirmed by bone scintigraphy. Under these circumstances the patient was referred to oncology department where two

sessions of chemotherapy with carboplatin and etoposid were followed by 2 shots of octreotide acetate. The thorax CT and the scintigraphy were repeated three months later and revealed an increase of the vertebral metastases. Due to electrolyte disturbances the patient was readmitted in the endocrinology department with severe low serum K (2.1 mmol/l), metabolic alkalosis and hyperglicemia.

The persistence of electrolyte disturbances led to the indication of bilateral adrenalectomy but in February 2010 the patient was admitted in the Intensive Care Unit for ventricular fibrillation due to refractory hypokaliemia. Despite intensive monitoring and therapy an acute myocardial infarction occurred and the patient died from cardiogenic shock and unresponsive cardiac arrest.

DISCUSSION

The carcinoid tumors of the thymus associated to Cushing's syndrome are aggressive tumors and usually produce local and distant metastases (3, 5). ^{18}F-FDG PET/CT, that integrates both functional and structural imaging in one device, can improve the accuracy of tumor localization in patients with ectopic Cushing's syndrome and further improve the prognosis of the patients by adequate treatment (6). The diagnosis represents a challenge to the endocrinologist as well as the therapy against life-threatening hypercortisolemia. Ectopic ACTH hormone secretion is more commonly associated with small cell carcinoma of the lung followed by islet cell cancer, medullary thyroid cancer, thymic carcinoid, pheochromocytoma and gastro-intestinal carcinoid. In 16% of patients, the tumor cannot be found, in this circumstance the patients are likely to benefit from a bilateral adrenalectomy (2). Clinicians should be aware of the patho-physiological changes of the thymus gland such as reactive thymic lymphoid hyperplasia, resulting from rapidly dropping cortisol levels occurring about six months after remission of hypercortisolism by medical treatment, in cases of still unknown primary tumor (7). The high dose dexamethasone suppression test showing lack of suppression along with CT scanning are the mainstay of the diagnosis (1, 4). ^{111}In and, more recently, ^{99m}Tc somatostatin analoques scintigraphy is a potentially useful imaging exploration in diagnosis and location of the carcinoid tumours, making evidence of intense uptake on the lesion (8, 9). Patients with ectopic ACTH secretion more likely present with persistent hypertension and hypokalemic metabolic alkalosis, which is resistant to huge doses of potassium supplementation. Profound hypokalemia and hypertensive crises from mineralocorticoid action of cortisol may lead to cardiac and vascular complications including ventricular arrhythmias. Medical therapy involves use of steroid synthesis inhibitors, such as Ketoconazole, Mitotane, Metyrapone, Octreotide, Amino-gluthethemide. Ketoconazole, which acts by blocking corticosteroid production by inhibiting 17-hydroxylase and 11- hydroxylase, is the therapy of choice because of its low incidence of side effects. Octreotide acts by binding to the sst2 somatostatin receptor, suppressing ACTH release. It is effective both on its own and in combination with Ketoconazole. Spironolactone, an aldosterone receptor antagonist, is used to decrease urinary potassium wasting secondary to activation of mineralocorticoid receptors. Surgery combined with medical therapy improves morbidity and quality of life. An important

feature of carcinoid tumors is their expression of somatostatin (SST) receptors. Somatostatin analogues are the best therapy for controlling the symptoms of malignant carcinoid syndrome. Octreotide has a half-life of approximately 1.5 hours and can be given as a subcutaneous or intravenous injection. SST analogues have been shown to be the best therapy for controlling carcinoid symptoms. In some studies, it has been shown that SST analogues inhibit tumour growth as monotherapy in up to 8% of treated carcinoid patients or even greater anti-tumour effect in combination with other agents, for example, interferon-α (10).

CONCLUSIONS

The reported case underlines the aggressiveness of the thymic carcinoids with ectopic ACTH secretion from the oncological point of view, but also regarding the refractory electrolyte disturbances with fatal outcome.

ARTERIAL AND VENOUS THROMBOSIS-TWO FACES OF THE SAME DISEASE. CASE REPORT (Abstract): Abnormal activation of the coagulation cascade in cancer patients leads to arterial and venous thrombotic events. If the link between venous thromboembolism and malignancy has long been known, cancer-related stroke is a newly recognized entity. We present the case of a 90-year-old woman who developed two concurrent ischemic strokes in the right posterior cerebral artery territory and deep vein thrombosis of the left lower limb, cascade of events that led to the diagnosis of a cancer. We highlight some of the particularities of cancer-related stroke to raise awareness upon this complication that leads to increased morbidity and mortality in cancer patients. We suggest that special attention should be paid to patients with concomitant thrombotic events in different vascular areas because a systemic underlying substrate may be involved. **Keywords:** CANCER, VENOUS THROMBOSIS, ARTERIAL THROMBOSIS, CANCER-RELATED STROKE.

Malignancy disturbs the hemostatic system and, consequently, the cancer patients are at high risk of both thrombosis and hemorrhage. Cancer cells activate the coagulation cascade by multiple mechanisms: tissue factor, inflammatory cytokines, cancer procoagulants, tumor mucins (1). The coagulation abnormalities may result in both venous and arterial thrombosis. Venous manifestations of cancer-associated thrombosis have been studied extensively. But in addition to venous thromboembolism (VTE), cancer-related stroke is emerging as a new severe complication of a malignancy.

CASE REPORT

We present the case of a 90-year-old woman who presented to our clinic for swelling of the left lower limb, with onset 7 days earlier and progressive worsening. The patient declared that she was hypertensive and a month earlier she suddenly developed complete loss of function in the left leg, being bedridden since then. At that time the patient did not seek medical advice. After 3 weeks of bed rest the left leg started to swell from calf to thigh. Due to the progressive worsening of swelling, the patient had been convinced by her family

to go to the hospital.

On admission the patient had high blood pressure (180/80 mmHg). She had sinus rhythm on ECG and minor ST segment abnormalities interpreted as expression of ischemic heart disease. The transthoracic echocardiography of the left heart revealed ventricular hypertrophy with normal systolic function and diastolic dysfunction (abnormal relaxation pattern), mild atrial dilatation. The mitral and aortic degenerative valvular changes were without hemodynamic significance. The evaluation of the right heart was normal. There were no discontinuities at the level of interatrial and interventricular septum. No cardiac sources of embolism were detected by transthoracic echocardiography. The left lower limb was plegic, with severe edema. The clinical signs were highly suggestive of deep vein thrombosis (DVT) of the left leg. Ultrasound examination confirmed the thrombosis of the left common and superficial femoral veins and of the popliteal vein (fig. 1). The patient needed to receive anticoagulant treatment. Prior to the initiation of anticoagulation, a craniocerebral computed tomography scan was performed. The presence of any expansive intracerebral processes and intracranial hemorrhages was excluded. Two areas of hypodensity, one of 14/18/15 mm located parasagittal frontal-parietal right and the other of 12/10/15 mm located on the topography of right semi oval center, were suggestive of subacute-chronic ischemic strokes in the territory of the terminal branches of the right posterior cerebral artery (fig. 2). The anticoagulant treatment was started with low molecular weight heparin (enoxaparin). After 5 days of anticoagulant treatment, a minor genital bleeding occurred. Abdominopelvic ultrasound was immediately performed. On the uterus topography, a nonhomogeneous hyperechogenic structure, with the largest diameter of 26 mm, highly suggestive for endometrial malignancy was found. The cancer antigen 125 (CA 125) serum level was 55.1 IU/mL, 2.6 times higher than the upper limit of the normal values. Invasive procedures were proposed to the patient, but she refused and asked her family to take her home. Only palliative recommendations were formulated at discharge.

Fig. 1. Ultrasound examination of the left leg. Recent, partially occlusive thrombosis of the left common femoral vein.

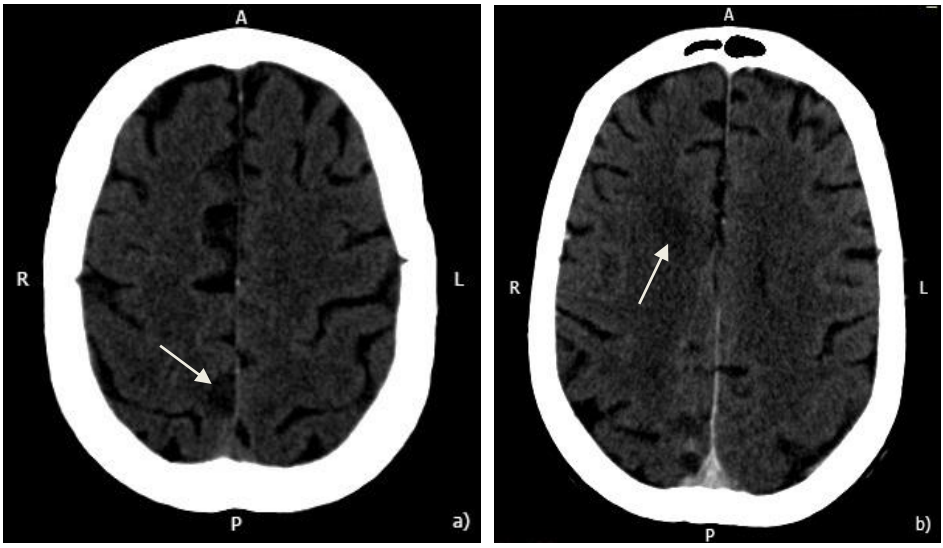

Fig. 2. Craniocerebral computed tomography with contrast enhancement. a) Area of hypodensity of 14/18/15mm located parasagittal frontal-parietal right; b) Area of hypodensity of 12/10/15 mm located on the topography of the right semi oval center.

DISCUSSION

Advanced age is associated with an increased risk for stroke. Atrial fibrillation, hypertension, atherosclerosis of extracranial and intracranial blood vessels, hyperlipidemia and diabetes mellitus are all highly prevalent in the elderly and they are also major risk factors for stroke. Due to immobility, stroke patients are at high risk for VTE, the pulmonary embolism ranking third among the most common causes of case fatality in stroke (2). Depending on the diagnostic methods, studies reported that up to 80% of patients with ischemic stroke who do not receive prophylactic therapy could developer DVT (3). In our case, we initially presumed that the patient suffered an ischemic stroke in the right posterior cerebral artery territory, with crural monoplegia, and as she was bedridden the venous stasis in the plegic leg favored the development of DVT. Dehydration, commonly found in the geriatric population and stroke patients, could also have contributed to the development of venous thrombosis.

The presence of the uterine tumor required reconsideration of the pathophysiological mechanism of these two vascular events. Thus, besides the venous stasis determined by immobilization and hemoconcentration due to dehydration, it was necessary to consider the imbalances that cancer brings upon hemostasis. It is well known that a malignancy increases the risk of DVT due to the alteration of one or more factors of the Virchow's triad. The tumor invades and compresses the surrounding structures, produces proinflammatory and prothrombotic mediators, thereby causing endothelial dysfunction, hypercoagulability and stasis. Patients with active cancer have a 4- to 8-fold increase in VTE incidence compared with the general population (4). The overall risk of VTE in patients with uterine cancer is relatively small, of 2.7%

in a 2-year incidence, but it can vary from 1.5% among women with local stage disease to 10.5% among women with advanced disease (5). It is very important to bear in mind that the presence of VTE in a patient with malignancy is a negative prognostic factor because in these patients the survival rate decreases up to 6-fold compared with patients without VTE (6). In patients with endometrial cancer, the elevated serum CA 125 concentrations are associated with deep myometrial invasion, extrauterine spread and reduced survival.

Although in the last decade there have been major changes in antithrombotic therapy due to the emergence of non-vitamin K antagonist oral anticoagulants (NOAC), low molecular weight heparin (LMWH) is still the guideline endorsed treatment of patients with cancer associated VTE (7). Old age (age > 75 years) is a bleeding risk factor in the anticoagulated general population whether the anticoagulant is warfarin, LMWH, or a NOAC (4). The anticoagulant therapy raises 2-6 folds the bleeding risk in cancer patients (8) and moreover patients who have the highest risk for VTE also have the highest risk for bleeding (4).

More recently, it has been studied the link between cancer and stroke. A malignancy may directly or indirectly lead to stroke. Several mechanisms have been proposed: direct tumor compression of blood vessels, hypercoagulability, non-bacterial thrombotic endocarditis and treatment-related effects (9).

As DVT may be the first manifestation of a malignancy (10), an ischemic stroke can also be the first manifestation of a cancer (1). Case reports linking stroke to cancer started to be published more than 10 years ago. In one case, stroke was the first manifestation of a concealed pancreatic neoplasia (11) and in another case a recurrent cerebral embolism led to the diagnosis of an ovarian cancer (12). One small study analyzed the clinical and imagistic particularities of stroke patients, whose cancers were diagnosed at stroke presentation (13) and it was emphasized that multiple cerebral infarctions of an unknown etiology must trigger the search of a concealed cancer. A study conducted on 348 consecutive patients with acute ischemic cryptogenic stroke, with and without cancer diagnosis, concluded that multiple infarcts involving multiple vascular territories are associated with the presence of malignancies (1414). One study reported that 67% of strokes in cancer patients appear on imaging as multiple concurrent embolic events, suggesting that clot formation and embolization are often responsible (15). This hypothesis is confirmed in our patient's case, by identifying two concurrent recent strokes, one located parasagittal frontal-parietal right and the other located on the topography of the right semi oval center. Moreover, gynecologic neoplasms are reported to have the highest potential for developing of ischemic stroke.

The most important mechanism linking cancer and stroke is the abnormal activation of the coagulation cascade. Tissue factor (TF) and cancer procoagulant (CP) are the most important procoagulant molecules that are release directly from the tumor cells (16). TF promotes thrombosis by activating the coagulation cascade after binding to Factor VII, while CP exerts its prothrombotic effect through the activation of Factor X. In one study, TF was identified in the atherosclerotic plaques of symptomatic patients with high-grade carotid artery stenosis, so it has been hypothesized that TF may destabilize the atherosclerotic plaques (17). A highly significant association of TF expression with the occurrence

of cerebral micro embolism was also found (17). Furthermore, tumor cells release cytokines such as tumor necrosis factor-alpha, interleukin-1 and interleukin-6 which are able to inhibit the natural anticoagulant pathway of C protein and to induce endothelial cells, monocytes, and cancer cells to express TF, thereby enhancing the thrombosis (9). So, the available data suggest that hypercoagulability-induced stroke is a real entity.

The anticoagulation with LMWH is the treatment of choice for VTE in cancer patients, but information regarding cancer-related stroke are lacking. The effect of anticoagulation on micro embolism was assessed in one study (18) and the results showed that anticoagulation has the potential to attenuate cancer-induced hypercoagulability leading to stroke. The recently published results of the OASIS-Cancer Study have demonstrated that the effective correction of hypercoagulability in patients with cancer-related stroke may play a protective role in survival of these patients (1). A risk score to estimate the need for anticoagulation for primary prevention of VTE in cancer patients already exist (19), but how to choose high-risk cancer patients to receive anticoagulation for stroke prevention is still a matter of debate and the role for antiplatelet in the secondary prevention of cancer-related stroke also remains to be investigated.

CONCLUSIONS

We present a case of concomitant arterial and venous thrombotic event to raise awareness upon the importance of identifying its underlying mechanism. Generally, the thrombotic events in the elderly people have a complex and multifactorial etiology. Through multiple mechanisms a neoplasia can disrupt the coagulation-fibrinolysis balance and it may trigger thrombotic events. Cancer must not be considered only a trigger for *in situ* vascular thrombosis or venous thromboembolism. We want to highlight that an active malignancy is associated with the activation of the coagulation cascade and of the inflammatory pathways in both the arterial and venous system and in patients with concomitant arterial and venous thrombotic events the presence of a systemic substrate should be investigated.

NEWS

AN INNOVATIVE SUTURING BIOMATERIAL WILL REINVENT THE SURGERY RECOVERY

A group of researchers from Donghua University, Shanghai, China conducted a very interesting study about synthesizing an "intelligent" biomaterial which is prepared successfully from bacterial cellulose and chitin and using it to obtain novel filament which can meet the demands of surgical sutures. The bacterial cellulose was used as a nanocrystals (BCNCs) for improving the mechanical performance of regenerated chitin (RC) fibers. These two materials have excellent biocompatibility and biodegradability with low toxicity when implanted in vivo. A detailed characterization comprising morphological observations, infrared spectroscopy, mechanical properties assessment, enzymatic degradability determination and in vitro biocompatibility and in vivo evaluations (murine skin wound closure) indicated that the BCNC/RC yarns meet the requirements for use as surgical sutures and promote wound healing without adverse effects (Huanling Wu, Gareth R. Williams, Junzi Wu, Jianrong Wu, Shiwei Niu, Heyu Li, Haijun Wang, Limin Zhu, Regenerated chitin fibers reinforced with bacterial cellulose nanocrystals as suture biomaterials, *Carbohydrate Polymers* 2017; 180: 304-313).

UN „FALD" CAPCANĂ ÎNTR-O BOALĂ TAKAYASU

L. Macovei, Gabriela Omete, Cătălina Arsenescu-Georgescu
Universitatea de Medicină şi Farmacie "Gr.T. Popa" Iaşi
Facultatea de Medicină
Institutul de Boli Cardiovasculare "Prof. Dr. George I.M. Georgescu" Iaşi

A TRAP „FOLD" IN A TAKAYASU ARTERITIS (Abstract): Sometimes, acute aortic dissection diagnosis, a significant cardiological and surgical emergency, is particularly difficult. Therefore, Takayasu arteritis associated dissection fold may be a real diagnostic „trap", in spite of all modern exploratory techniques. **Key words:** AORTIC DISSECTION, TAKAYASU ARTERITIS, DIAGNOSIS

Disecţia acută de aortă este o mare urgenţă cardiologică şi chirurgicală, mortalitatea în cazul bolii netratate fiind de 1% pe oră, în primele 24 de ore, ajungând în urgenţă, în cazul bolii netratate chirurgical până la 90% la 3 luni de la diagnostic. Cu toate mijloacele moderne de diagnostic şi progresele din chirurgia cardiovasculară, mortalitatea în disecţia de aortă rămâne mare (rata de supravieţuire la un an într-un studiu multicentric european a fost de 52% în tipul I, 69% în tipul II şi 55% în tipul III) (1).

Evidenţierea prin diferite metode a unui fald de disecţie poate fi uneori extrem de dificilă. Această situaţie se regăseşte şi în următoarea prezentare de caz clinic, în care prezenţa unei comorbidităţi – boala Takayasu (o posibilă cauză de disecţie de aortă) – a indus importante dificultăţi în confirmarea sau infirmarea ipotezei de disecţie acută a aortei.

Boala Takayasu este o afecţiune idiopatică rară, caracterizată printr-o inflamaţie vasculară cronică care afectează aorta şi ramurile sale mari, inclusiv arterele coronare, carotide, pulmonare şi renale (2, 3, 4). În evoluţie se produce fibroza pereţilor arterelor afectate, cu apariţia manifestărilor clinice specifice stenozelor sau ocluziilor arterelor dintr-un anumit teritoriu, formării de anevrisme care pot evolua spre disecţie (2, 5, 6).

PREZENTAREA CAZULUI

Pacienta S.A., în vârstă de 43 ani, se adresează în urgenţă clinicii noastre cu ipoteza de diagnostic – Disecţie acută de aortă, ipoteză susţinută de examenul CT toracic. Pacienta este internată în Unitatea de Terapie Intensivă Coronarieni, motivele fiind: durere retrosternală de repaus cu iradiere în braţe, interscapulară şi la baza gâtului, accentuată de mişcările corpului, cu durata de aproximativ 3 ore şi fără răspuns la nitroglicerină sublingual, survenită cu 24 ore anterior internării, dispnee la eforturi mici; actual asimptomatică. Antecedentele personale patologice ale pacientei sunt importante. Astfel, de la vârsta de 30 ani pacienta este diagnosticată cu boală Takayasu (inclusiv prin angiografie), ocluzie de arteră subclaviculară stângă, insuficienţă aortică gradul III şi hipertensiune arterială esenţială. Este nefumătoare, neagă consumul cronic de alcool şi desfăşoară o activitate intelectuală. Din istoricul bolii reţinem şi apariţia de aproximativ un an a dispneei la eforturi mici şi a unor dureri retrostenale de efort tipic anginoase (spre deosebire de durerea

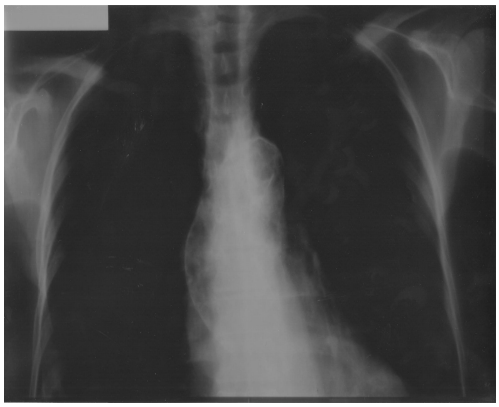

Fig. 1. Radiografia toracică

Fig. 2. Ecocardiografia transtoracică

toracică care a determinat internarea actuală). Ultimul tratament urmat a fost cu perindopril 2,5mg/zi şi pentoxifilin 800 mg/zi.

La examenul obiectiv, datele patologice înregistrate au fost : puls regulat, tahicardic (100/min.) ; TA braţ drept – 70/40 mmHg ; TA braţ stâng – nemăsurabilă ; TA coapse – 200/60 mmHg ; suflu diastolic de regurgitare aortică ; suflu sistolic carotidian stâng ; puls absent la artera radială şi humerală stângă şi diminuat pe dreapta, artere femurale pulsatile bilateral, fără semne de ischemie acută periferică.

În acest moment ne-am întrebat dacă avem de-a face sau nu cu o urgenţă majoră, ipotezele de diagnostic clinic fiind :

- Disecţie acută de aortă.
- Sindrom coronarian acut.
- Durere pericardică.
- Durere de perete toracic.

Biologic s-au evidenţiat : sindrom inflamator nespecific moderat : VSH 24 mm/1 oră, fibrinogen 587 mg%, GA 14000/mm^3, CRP 8,5 mg/l ; metabolism lipidic şi glucidic normal ; markeri de necroză miocardică fără creştere patologică : CK-MB 17 u/l, TGO 20 u/l, LDH 443 u/l, TnT negativă ; funcţie hepatică şi renală normală ; D-dimeri absenţi.

Electrocardiograma relevă : tahicardie sinusală 95/min ; HVS ; unde T ample, pozitive simetrice în V1-V4.

Radiografia toracică evidenţiază aorta intens calcificată (Fig. 1).

Ecocardiografia transtoracică efectuată în urgenţă a relevat (Fig. 2, Fig. 3) : VS dilatat, cu disfuncţie sistolică şi diastolică (FE 35%, FS 18%, DTDVS 58 mm, DTSVS 48 mm, SIV 10 mm, PP 9 mm, DSM 18 mm, VTDVS 141 ml, VTSVS 84 ml, E/A > 1) ; insuficienţă aortică gradul IV ; aortă intens calcificată, de dimensiuni normale ; posibil „fald" de disecţie de la nivelul inelului aortic şi până la jumătatea crosei, paralel cu peretele anterior aortic ; absenţa lichidului pericardic.

Ecografia abdominală : aortă abdominală intens calcificată, de dimensiuni normale, dar cu posibil fald de disecţie sub emergenţa arterei renale stângi.

Tomografia computerizată efectuată anterior internării : aortă de dimensiuni normale, intens calcificată ; disecţia aortei ascendente toracice pe o lungime de 17 mm, cu punct de plecare supravalvular (Fig.4) ; posibilă disecţie a aortei abdominale – 11 mm, caudal de emergenţa arterei renale stângi (Fig. 5).

În evoluţie, pacienta prezintă o durere retrosternală, cu răspuns prompt la nitroglicerină sublingual şi accentuarea discretă a modificărilor de fază terminală în teritoriul inferolateral.

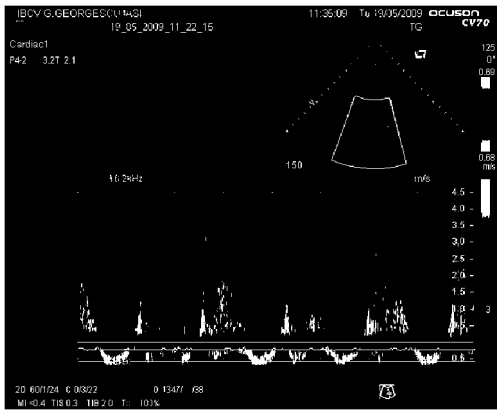

Fig. 3. Ecocardiografia transtoracică

În continuare, principala problemă a fost diagnosticul de urgenţă cardiovasculară, în această etapă ipotezele de diagnostic rămânând :

1. Disecţie acută de aortă :

- argumente : tomografia computerizată, ecocardiografia, ecografia abdominală ;
- „ciudat” : disecţie concomitentă a aortei în 2 teritorii strict limitate aflate la distanţă.

2. Angină pectorală instabilă :

- argument : modificări de fază terminală în dinamică ;
- contraargument : caracterul atipic al durerii anginoase prelungite.

Diagnosticul de certitudine a fost tranşat prin angiografie care a evidenţiat :

- aorta ascendentă, crosa şi aorta descendentă sever calcificate ;
- stenoză 95% a arterei subclaviculare drepte ;
- ocluzia arterei subclaviculare stângi, stenoză 40% a arterei carotide comune stângi ;
- subocluzie de arteră vertebrală stângă ;
- coronare cu plăci ateromatoase difuze, fără stenoze semnificative ;
- insuficienţă aortică gradul IV, fără elemente de disecţie a aortei, artere renale permeabile.

În acest context, diagnosticul final a fost :

Fig. 4. Tomografia computerizată toracică

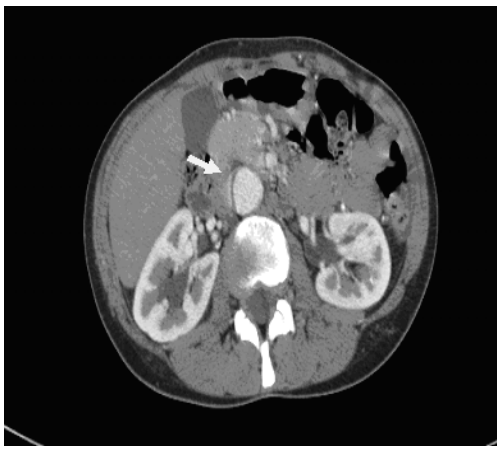

Fig. 5. Tomografia computerizată abdominală

1. Angină pectorală de efort
2. Boală Takayasu
3. Ocluzie arteră subclaviculară stângă
4. Stenoză arteră subclaviculară dreaptă
5. Stenoză arteră carotidă comună stângă
6. Insuficienţă aortică gradul IV
7. Cardiopatie hipertensivă
8. Insuficienţă cardiacă cronică clasa III NYHA

Probleme terapeutice au fost :

- scăderea TA (măsurată la nivelul coapsei) până la valori care să nu determine

fenomene ischemice cerebrale sau la nivelul membrelor superioare ;
- tratamentul insuficienţei aortice, cu indicaţie de protezare valvulară, dar cu risc intraoperator extrem de mare, rezultat din calcificarea intensă a aortei ascendente ;
- tratamentul leziunilor stenotice/ocluzive arteriale prin angioplastie cu stent sau *by-pass* când se impune, proceduri de asemenea cu risc crescut.

DISCUŢII

Principala problemă în cazul prezentat a fost diagnosticul diferenţial între faldul de disecţie şi peretele aortic intens calcificat în contextul bolii Takayasu. Arterita Takayasu este o vasculită granulomatoasă de etiologie neprecizată, mai frecventă la femei, care afectează aorta toracică, abdominală şi ramurile mari ale acestora. A fost descoperită în 1908 de oftalmologul Mikito Takayasu, care a descris modificările specifice de la nivelul vaselor oculare la o femeie japoneză în vârstă de 21 ani. Boala are un prognostic rezervat, mortalitatea fiind de 75% fără tratament şi de 10% cu tratament. Complicaţiile arteritei Takayasu sunt multiple, o bună parte regăsindu-se sau punând probleme de diagnostic diferenţial în cazul prezentat : HTA (prin reducerea fluxului sanguin renal), insuficienţa aortică, insuficienţă cardiacă, angină pectorală, infarct miocardic acut, anevrisme aortice care pot diseca, etc.

CONCLUZII

Cazul este particular prin dificultatea şi complexitatea diagnosticului diferenţial dintre „faldul" de disecţie şi peretele aortic intens calcificat în contextul bolii Takayasu, o afecţiune vasculară rară, severă, cu multiple complicaţii arteriale. De asemenea, în acelaşi context, subliniem limitările terapeutice importante : protezare aortică dificilă tehnic datorită aortei ascendente intens calcificate ; controlul tensiunii arteriale în contextul leziunilor de pe arterele carotide şi subclaviculare.

THE MANAGEMENT OF SKIN TUMORS EXTENDED TO THE ORBIT (Abstract) **Aim:** This paper focuses on presenting the experience of the authors on the management of orbital invasion from periocular skin malignancies. **Material and methods:** We reviewed 18 cases of skin tumors extended to the orbit regarding the initial location, clinical signs, diagnostic methods, the surgical treatment and reconstruction procedure, the tumor histology, as well as the postoperative outcome and complications. **Results:** The most encountered location of the malignancy was at the level of the inferior eyelid. The predominant histological type was squamous cell carcinoma, followed by basal cell carcinoma and glandular carcinoma. Thirteen of the included patients underwent orbital exenteration, with five necessitating an extended orbital exenteration to the neighboring structures. Various reconstructive procedures were used for closure considering the extent of the defect, ranging from split thickness skin graft, local and regional flaps, to microvascular free flaps. The overall postoperative results were favorable with accurate defect coverage and few complications. **Conclusions:** Orbital invasion by skin malignancies can be adequately managed by orbital exenteration and a closure method suitable to the extent of the postoperative defect, the patient's age and comorbidities. **Keywords:** ORBITAL EXENTERATION, ORBITAL INVASION, SKIN CANCER, RECONSTRUCTION.

Periorbital non-melanoma cutaneous malignancies are common encounters, making up for approximately 5 to 10 % of all skin cancers (1). Basal cell carcinoma is the main type of malignancy involving the periorbital skin, representing approximately 90% of lesions. It is more commonly found on the inferior eyelid and medial canthal area, while sebaceous gland carcinoma is encountered mainly in the superior eyelid region. Squamous cell carcinoma and sebaceous gland carcinomas each account for less than 10% of periocular skin malignancies. Orbital invasion is reported in less than 4% of cases and it is a more likely occurrence in older patients with neglected large lesions located in the medial canthal area, in patients with a history of previously excised skin malignancies and the presence of local recurrence, as well as in association with aggressive histologic subtypes and the ones expressing perineural invasion (2, 3).

The infiltration of intra-orbital structures can be clinically silent in one third of cases (1). If not accurately diagnosed, it can lead to residual tumor and the onset of local recurrence, with a worse overall prognosis. Clinically apparent orbital invasion is generally associated with large ag-

gressive tumors and the surgical treatment can therefore lead to significant morbidity and deformity. The indications for orbital exenteration must be carefully considered for ensuring oncologic safety with minimal morbidity. The accurate diagnosis of the extent of tissue invasion and proper surgical planning can help decide the best option.

The purpose of this paper is to present our experience regarding the surgical management of skin tumors with orbital extension, focusing on the main challenges encountered regarding the extent of tissue removal, the options for reconstruction and the associated complications.

MATERIAL AND METHODS

We performed a review of patients diagnosed with periocular skin malignancies in between January 2013 and April 2018. We included only the patients who had clinical or imaging evidence of orbital invasion and were diagnosed with non-melanoma skin cancer. Patients with unresectable tumors were excluded from the study, as well as patients who did not undergo tumor removal due to contraindication or due to the patient's refusal. Patients diagnosed with skin invasion from malignancies arising in the adjacent orbital or sino-nasal structures, according to the history of the disease and the final histology, were also excluded from the study. The medical charts of all 18 patients included in the study were analyzed for information regarding the clinical signs, the tumor location and size, the diagnosis of orbital invasion, the type of tumor removal procedure and reconstruction, the postoperative complications and outcomes.

RESULTS

A total of 18 patients with non-melanoma skin cancer extended to the orbit were identified. There were 11 men (61.1%) and seven women (38.9%), aged between 57 and 83 years old. Three (16.6%) patients had recurrent tumors from previously operated carcinomas in the same region. Four (22.2%) of them had performed preoperative radiotherapy. Three (16.6%) patients had a history of skin cancer surgery in other head and neck regions, and two (11.1%) patients had previous surgery for cutaneous malignancies in other regions of the body. There were 11 (61.1%) cases of SCC (squamous cell carcinoma), six (33.3%) BCC (basal cell carcinoma) and one (5.6%) glandular carcinoma. The initial location of the tumor was at the level of the inferior eyelid in eight cases (44.4%), the superior eyelid in five patients (27.7%), the medial canthus in two (11.1%), lateral canthus in one patient (5.6%), the nasal region in one case (5.6%), the genian region in one patient (5.6%). Upon presentation, 15 (83.4%) patients had clinical signs suggestive for orbital invasion, consisting of exophthalmos in six patients (33.3%), globe displacement in five patients (27.7%), limited eye movements in four cases (22.2%), diplopia in six patients (33.3%), infraorbital hypoesthesia in two cases (11.1%), visual impairment in seven patients (38.9%) and tumor adherent to the subjacent bone on palpation in nine patients (50%). In the other three (16.6%) cases, the patients had no obvious clinical signs of orbital invasion. Paraclinical investigations CT in 12 (66.6%) cases and MRI in 9 (50%) patients were necessary for determining the tumor spread and diagnosing orbital invasion. Associated clinical findings and symptoms were the presence of a palpable mass in 18 cases (100%), pain in seven patients (38.9%), bleeding in 14 (77.7%), epiphora in six cases (33.3%). The greatest external tumor diameter was 6

cm, while the smallest tumor was 3 cm. None of the patients with squamous cell carcinoma had lymph node metastasis upon presentation.

Tumor removal was performed in all patients after histological confirmation by incisional biopsy. Exenteration was performed in 13 (72.3 %) cases and an extended orbital exenteration was necessary in five (27.7%) patients. Partial preservation of one or both eyelids was performed in eight (44.4%) cases. The exenteration defect was covered by a split thickness skin graft in three patients (16.6%), by an association of local and regional flaps in two cases (11.1%), a temporalis muscle flap in five patients (27.7%), a lateral pedicled frontal flap in association with titanium mesh in three patients (16.6%), a lateral pedicled frontal flap in two cases (11.1%), one medial pedicled frontal flap (5.6%), one major pectoralis muscle flap (5.6%) and one latissimus dorsi flap (5.6%).

The postoperative results were favorable regarding the complete tumor removal and obtaining an accurate defect closure with a short healing time. The postoperative scars and resulting deformity due to the absence of the orbital tissues could be easily camouflaged by wearing an eye patch. During the postoperative time there were few local complications that resolved by local and systemic treatment methods. They included partial flap necrosis in three cases (16.6%), wound dehiscence and infection in two patients (11.1%), bone exposure and delayed secondary healing of the exenteration socket in two patients (11.1%). There was one (5.6%) case of intraoperative cerebrospinal fluid fistula that was managed using a latissimus dorsi flap. Five (27.7%) patients underwent postoperative radiotherapy. Follow-up at one month, three months and six months did not show any signs of tumor recurrence.

The good postoperative outcomes are exemplified by the help of a clinical case (fig. 1-5).

DISCUSSION

The management of cutaneous tumors with orbital invasion differs regarding the extent of tissue removal in the presence of various patterns of orbital invasion and histologic types. In our study, clinical or radiological evidence of orbital invasion, consisting of tumor tissue extending beyond the orbital septum, into the orbital fat, was an indication for orbital exenteration in all cases to ensure complete tumor removal and decrease the recurrence rate. This is consistent with most of the existing literature on the subject, but there are also authors that suggest a more conservative approach, opting for globe-sparing procedures in anterior orbital invasion from basal cell carcinoma (4, 5, 6, 7).

The slow local invasion and the absence of lymphatic spread, characteristic for most subtypes of basal cell carcinomas, may allow a less aggressive tissue removal. However, basal cell carcinoma in the periocular region is generally associated with more aggressive types considering the growth pattern, such as infiltrative, morpheic and basosquamous (4, 8, 6). Perineural spread is also exhibited by some histological types and it is a major cause of local recurrence. Additionally, the location of malignancy development in the periocular skin, particularly the medial canthal region and superior nasal-genian fold region favor the deep spread of tumor at the junction of various anatomical elements. Residual tumor may grow extensively before a recurrence diagnosis is made. In consideration of all these factors, we consider advisable to perform an initial orbital exenteration for malignancies eroding through the orbital septum into the orbital fat, regardless of the histology. Complete or partial preservation of an eyelid and conjunctiva can be performed without compromising oncologic safety in most cases, considering the location of the cutaneous malignancy. This aspect is important for obtaining better aesthetic results of the orbital socket reconstruction (9).

Although less common than basal cell carcinoma in the periocular region, squamous cell carcinoma is responsible for most cases of orbital invasion that require orbital exenteration procedures (10). We found similar results in our case series, consisting of 61.1% squamous cell carcinoma cases out of the total.

Due to its aggressive rapid growth pattern and possibility of lymphatic and hematogenous metastasis, cutaneous periorbital squamous cell carcinoma requires an initial radical resection, involving an orbital exenteration for all malignancies invading beyond the orbital septum. The controversy is regarding lymph node dissection in the presence of a high-risk situation and absence of macroscopic nodes. Lymph node metastases from periocular squamous cell carcinoma may be encountered in up to 25% of cases. Laterally located orbital malignancies drain mostly in the intraparotid and peri parotid lymph nodes, while medial tumors drain via the angular and facial vein into the facial and submandibular lymph nodes (11). The same tumor characteristics associated with a higher risk of orbital invasion, are also related to a higher rate of lymph node metastasis for squamous cell carcinoma lesions: increased tumor size, recurrence of previously operated tumors, the depth of invasion, less differentiated histologic subtypes, perineural spread, patient over 70 years of age (12, 13). In our study we did not encounter any patient with lymph node involvement at the time of the initial presentation, despite the

presence of some of the mentioned features associated with a higher risk for lymphatic metastasis. In the absence of clinically or imaging lymph node involvement, we did not consider necessary to perform a prophylactic lymph node dissection. This is the general management preferred by most surgeons, although some advocate for sentinel node biopsy in high-risk cases (11, 14). With absence of lymph node removal, a careful oncologic surveillance is crucial for the early detection of possible lymphatic metastasis.

Considering the extent of the postoperative defect, several techniques may be used for closure. The simple orbital exenteration socket heals by secondary intention through granulation tissue formation that takes place over three to four months (15). Covering the socket with a split thickness skin graft can shorten the healing interval. If radiotherapy is planned postoperatively, a good, rapid healing of the socket is desired, thus a local or regional flap may be used. For defects involving the bony walls of the orbit and the neighboring anatomical structures, opening the adjacent sinus cavities (6, 16), a regional flap or a free flap is often necessary. Due to the advanced age of the patients and comorbidities, we preferred the covering of the orbital socket using a split thickness skin graft when the orbital walls were intact, without communication with the adjacent sinus cavities. This method allowed shorter surgery time, good results, decreased complications, good oncologic surveillance by direct inspection of the orbital socket, and the possibility to start postoperative radiotherapy. In defects involving the bony walls, we favored the use of local and regional flaps for closure, with good overall results and few complications. Extended defects involving a wide skin surface and a wide opening of adjacent cavities, or associating a cerebrospinal fluid fistula, were closed using a free flap.

Almost one quarter of orbital exenteration procedures are followed by the onset of complications (15). Studies have found similar complications to the ones encountered in our case series, including exposed bone with prolonged healing of the residual socket, fistula formation and chronic drainage, tissue necrosis and infection, pain (15, 17). Most complications were managed conservatively, without the need for invasive procedures. We encountered one case of intraoperative cerebrospinal fluid fistula consecutive to the removal of the extended tumor. The closure of the fistula was achieved using a latissimus dorsi flap that was also necessary for covering the remaining skin defect and the exenteration socket.

The main purpose of surgery is achieving local control of the disease and adequate closure of the defect for a rapid postoperative healing, in detriment to the aesthetic result. Secondary procedures can be performed for improving cosmesis. An orbital epithesis can be performed to recreate the lost facial features, to decrease the psychological impact of the resulting deformity and increase social integration of the patients. Since the manufacturing of a natural looking epithesis with a good adaptation and comfortable wear is challenging, most patients prefer wearing an eye patch for camouflaging the reconstructed region.

CONCLUSIONS

We found that cutaneous malignancies invading the orbit can be adequately managed surgically by orbital exenteration and extended orbital exenteration with good results and few complications. A variety of

techniques can be employed for the closure of defects with various extents. The challenges encountered were choosing the most appropriate method for individual defect reconstruction in the presence of comorbidities and advanced age, as well as establishing the opportunity of performing a prophylactic lymph node dissection for orbital squamous cell carcinoma in the absence of clinically or imagistic nodal involvement. Postoperative surveillance is crucial for patients with orbital invasion for the early detection of local recurrence and lymph node metastasis.

NEFRITA HENOCH-SCHONLEIN: PROBLEME DE DIAGNOSTIC ŞI PROGNOSTIC LA COPIL

Maria Adriana Baltag[1], O. Brumariu[1], Mihaela Munteanu[1], Doina Mihăilă[2]
Universitatea de Medicină şi Farmacie "Gr.T. Popa" Iaşi
Facultatea de Medicină
Spitalul Clinic de Urgenţe pentru Copii "Sf. Maria" Iaşi
1. Clinica a IV-a Pediatrie
2. Laboratorul de Anatomie patologică

HENOCH-SCHONLEIN NEPHRITIS: DIAGNOSIS AND PROGNOSIS PROBLEMS IN CHILDHOOD (Abstract): Henoch-Schonlein purpura (HSP) is the most common vasculitis in childhood and is characterized by sistemic leukocytoclastic angiitis, mainly affecting small vessels of the skin, joints, gastro-intestinal tract and kidneys. Renal involvement is the most important cause of morbidity and mortality in patients with HSP. The aim of this study was to evaluate renal involvement in children with HPS and the prognoses of short- and long-term outcome of patients diagnosed with HS nephritis. **Material and method**: We conducted a retrospective study based on observation files of hospitalized children with Henoch-Schonlein purpura admitted in the Nephrology Department" Sf. Maria" Hospital, during 20 years. **Results**: The results showed that the prognosis of Henoch-Schonlein nephritis is relatively good and long-time morbidity is predominantly associeted with initial presentation and renal involvement. **Key words**: HENOCH-SCHONLEIN PURPURA, CHILDHOOD, OUTCOME, HENOCH-SCHONLEIN NEPHRITIS

Purpura Henoch-Schonlein (PHS) este cea mai comună vasculită întâlnită în copilărie. Este o afecţiune multisistemică ce afectează în general pielea, articulaţiile, tractul gastro-intestinal şi rinichii, dar pot fi interesate şi alte organe. Leziunea vaselor mici este mediată de imunglobulinele A. Afectarea renală este importantă deoarece fixează prognosticul bolii.

Ne-am propus, printr-un studiu retrospectiv, evaluarea manifestării renale şi a prognosticului pe termen scurt (sub 6 luni) sau lung (peste 6 luni) a pacienţilor diagnosticaţi cu PHS. Cazurile au fost internate şi urmărite în Clinica a IV-a Pediatrie, UMF „Gr.T. Popa" Iaşi.

MATERIAL ŞI METODĂ

Au fost urmăriţi 39 de pacienţi, internaţi într-un interval de 20 de ani în Clinica a IV-a Pediatrie, care au îndeplinit cel puţin 3 din cele 6 criterii ACR (American College of Rheumatology) modificate (1). S-au evaluat datele clinice iniţiale, datele epidemiologice şi principalele modificări urinare. Am încercat aprecierea evoluţiei pe termen scurt şi lung a nefritei Henoch-Schonlein (NHS) sub diferite scheme de tratament.

Am urmărit durata şi persistenţa modificărilor renale la toţi pacienţii cu NHS.

Parametrii utilizaţi au fost:

a) Clinici: hematuria macroscopică; edemele; oliguria; hipertensiunea arterială (HTA).
b) Biologici: creatinina serică şi rata de filtrare glomerulară - RFG (calculată după formula Schwartz), proteine totale, albumina serică, lipide totale, colesterol.
c) Urinari: hematuria microscopică (testul Addis), proteinuria pe 24 ore.

d) Histologici : puncţia biopsie renală (PBR) a fost efectuată în 10 cazuri. Criteriile de PBR au fost : persistenţa proteinuriei (peste 1,5 g pe 24 ore), prezenţa sindromului nefrotic sau nefritic şi scăderea RFG. La pacienţii la care s-a practicat PBR s-a urmărit corelaţia dintre substratul histologic şi evoluţia pe termen scurt sau lung.

Pacienţii cu NHS au fost împărţiţi în 5 grade în funcţie de manifestările clinice iniţiale conform clasificării Meadow (2) modificate :

Gradul I - hematurie microscopică : 12 cazuri (38,5%)

Gradul II - proteinurie medie persistentă (<1,5 g pe 24 ore) ± hematurie : 11 cazuri (28,2%)

Gradul III - sindrom nefritic parţial : hematurie, scăderea RFG, oligurie, HTA, edeme : 11 cazuri (28,2%)

Gradul IV - sindrom nefrotic : proteinurie >50 mg/kgc/zi, hipoalbuminemie, hiperlipidemie, edeme : 2 cazuri (5,1%)

Gradul V - nefrită/nefroză : 3 cazuri (7,7%).

Pentru aprecierea evoluţiei pacienţii au fost încadraţi în 2 grupe :

Grupul I a cuprins gradele I şi II (23 cazuri).

Grupul II a cuprins gradele III, IV, V (16 cazuri).

g) Tipul de tratament utilizat : anticoagulant (tip I), corticoterapie orală (tip II) şi alte imunosupresive : pulsaţii de Metilprednisolon, Ciclofosfamidă (tip II).

h) Evoluţia a fost clasificată conform criteriilor Meadow (2) :

- A - normală : fără HTA, modificări urinare, creatinina serică normală
- B - modificări urinare minime : proteinurie minimă ± hematurie macroscopică sau microscopică recurentă
- C - boală renală activă : proteinurie >50 mg/kgc/zi, creşterea creatininei serice
- D - insuficienţă renală cu scăderea RFG <60 mL/min/1,73m^3

Evoluţia pe termen - scurt : până în 6 luni şi - lung : mai mult de 6 luni

Datele au fost încărcate şi prelucrate cu ajutorul funcţiilor statistice din EXCEL, EPIINFO şi SPSS.

REZULTATE

Parametri clinici

Manifestarea renală exprimată clinic prin sindrom nefritic a fost întâlnită la 71,8% dintre pacienţii cu PHS. Remarcăm faptul că sexul feminin asociază mai frecvent afectare renală comparativ cu cel masculin, diferenţa fiind statistic seminificativă între sexe ($p=0,03$), dar nu şi raportat la vârsta pacientului ($p>0,05$).

Parametri biologici

a) Retenţia azotată ca manifestare a NHS a fost întâlnită la debutul afecţiunii la 30,8% dintre cazuri, 53,8% aveau o RFG normală în momentul diagnosticului, iar 15,4% din cazuri nu aveau creatinina lucrată la debut. Remarcăm normalizarea valorilor creatininei (de la 1,44 la 1,17 mg%) şi creşterea RFG (de la 87 la 93,9 mL/min/1,73m^3) la pacienţii cu retenţie azotată la debut, pe parcursul derulării studiului, ceea ce sugerează o evoluţie favorabilă.

b) Hipoproteinemia, ca expresie a sindromului nefrotic asociat nefritei HS s-a întâlnit în 20,5% dintre cazuri. Se remarcă o corelaţie indirectă, slabă ($r = -0,14$) între valorile scăzute ale proteinelor totale şi valoarea crescută a creatininei, precum şi o corelaţie directă ($r = +0,44$) între normalizarea RFG şi valoa-

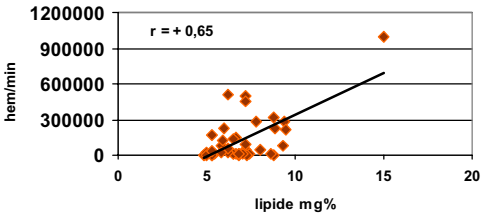

Fig. 1. Corelaţia dintre lipide şi hematurie la pacienţii cu NHS

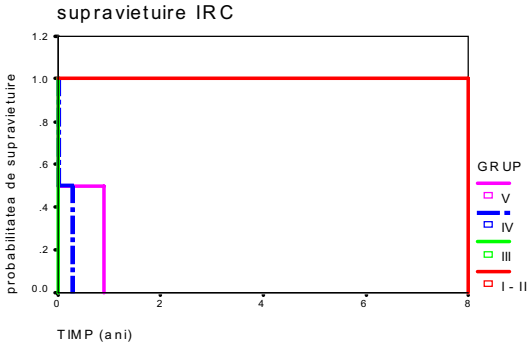

Fig. 2. Curba de supravieţuire Kaplan-Meier în funcţie de perioada de monitorizare, valorile hematuriei şi evoluţia spre IRC

rea normală a proteinelor totale. Se poate spune că hipoproteinemia influenţează negativ RFG.

c) Hipercolesterolemia a fost întâlnită la debut doar la 12,8% dintre cazuri. Aparent se remarcă faptul că valorile colesterolului cresc odată cu creşterea creatininei serice, dar dislipidemia (valori crescute ale lipidelor totale şi ale colesterolului) nu reprezintă un factor de progresie a leziunilor de NHS .

Parametri urinari

a) Hematuria microscopică a fost prezentă la 66,7% dintre pacienţi la debut. Remarcăm o corelaţie directă slabă între hematuria microscopică şi valorile mari ale creatininei serice (r = +0,27) şi o corelaţie indirectă (r = -0,32) între hematuria masivă şi scăderea RFG. Există însă o puternică corelaţie directă (r = +0,68) între hematurie şi hiperlipidemie (fig. 1).

b) Proteinuria de rang nefritic a fost întâlnită la 38,5% dintre cazuri şi cea de rang nefrotic la 17,9% la debutul studiului. Proteinuria a diminuat pe parcursul monitorizării lotului, ca efect al terapiei instituite, fără ca aceasta să fie statistic semnificativă (p > 0,05).

c) Pentru aprecierea evoluţiei NHS pe parcursul desfăşurării studiului, cazurile au fost încadrate în 5 grade conform clasificării Meadow (2).

Cele mai multe cazuri de NHS (87,2%) sunt incluse în gradele I, II şi III conform clasificării Meadow. Cea mai lungă perioadă de supravieţuire de organ se întâlneşte la cei cu afectare renală gradul I (manifestată doar prin hematurie microscopică), iar supravieţuirea este scăzută la cei incluşi în gradul V (cu manifestări de nefrită/nefroză), ajungând la maxim 12 luni.

Pacienţii cu gradele I şi II de afectare renală au o evoluţie favorabilă pe termen scurt, care diferă semnificativ statistic (p = 0,0009) comparativ cu cea de la pacienţii cu gradele III, IV, V.

În 6 cazuri (15,4%), pacienţii au evoluat spre IRC terminală şi au necesitat supleerea funcţiei renale prin dializă. În ceea ce priveşte evoluţia pe termen lung, aceasta este de asemenea favorabilă la pacienţii cu gradele I şi II de afectare renală, conform clasificării Meadow , comparativ cu cei care se încadrează în gradele III, IV şi V, diferenţele dintre ele fiind semnificative statistic (fig. 2).

În funcţie de clasificarea Meadow am subîmpărţit lotul de studiu în două grupuri, pentru a studia evoluţia nefritei Henoch-Schönlein către IRC şi dializă :

Grup I : în care intră gradele I şi II din clasificarea Meadow - 23 pacienţi (59%)

Grup II : în care intră gradele III, IV şi V din clasificarea Meadow - 16 pacienţi (41%).

Evoluţia, clasificată după criteriile Meadow, se poate observa în tabelul I.

Se remarcă din acest tabel că un singur pacient clasat în grupul II a prezentat evoluţie încadrată în grupul D. În acest caz, afectarea renală nu a fost investigată la debut, nefiind posibilă încadrarea corectă.

Astfel, prezenţa sindromului nefritic sau nefrotic, precum şi manifestările tip nefrită/nefroză la debul PHS se asociază cu evoluţie nefavorabilă atât pe termen scurt cât şi pe termen lung, influenţând net supravie-

Clasa III	1	A	A
	6	B	B
Clasa IV	1	D	D
Clasa IV/V	1	C	D

ţuirea renală.

Evoluţia sub tratament a fost favorabilă de asemenea la pacienţii din grupul I (gradele I şi II Meadow de afectare renală). Din cele 16 cazuri incluse în grupul I, la 10 s-a obţinut remisiunea completă la 6 luni de urmărire şi doar la 8 s-a menţinut această remisiune (tab. II). Majoritatea acestor pacienţi au primit corticoterapie oral.

Pacienţii cu sindrom nefritic au avut o evoluţie pe termen lung relativ favorabilă : din cele 10 cazuri, 9 au continuat să prezinte doar hematurie microscopică şi/sau proteinurie.

Cazurile cu sindrom nefrotic au avut evoluţie nefavorabilă pe termen lung, cu scăderea RFG sub 60 mL/min/1,73 m^3. Se poate afirma că proteinuria de rang nefrotic este factor de prognostic nefavorabil pentru NHS.

Puncţia biopsie renală a fost efectuată în 10 cazuri, iar în 2 din cazuri a fost necesară repetarea ei, datorită evoluţiei nefavorabile. Se poate remarca evoluţie favo-

rabilă în cazul NHS clasă II şi doar într-un singur caz de NHS clasă III, celelalte cazuri de NHS au evoluat cu persistenţa modificărilor urinare minime (proteinurie < 1 g%o ± hematurie).

Clasa IV de NHS a avut o evoluţie nefavorabilă atât pe termen scurt cât şi lung.

DISCUŢII

În lotul studiat majoritatea pacienţilor (71,8%) diagnosticaţi cu PHS au asociat la debut manifestări renale: HTA (43,6%), edeme, oligurie. Evoluţia lor a fost relativ favorabilă, dar aceşti pacienţi au fost urmăriţi pe o perioadă relativ scurtă de timp: media a fost de 34,22 luni, cu limite între câteva zile şi 124 de luni. Unii pacienţi nu s-au mai prezentat la control şi astfel evoluţia lor nu a putut fi apreciată. În literatură se citează necesitatea urmăririi evoluţiei pe o perioadă de cel puţin 10 ani (supravieţuirea renală la 10 ani a fost de 73%). Scharer et al. au efectuat un studiu cu privire la evoluţia la 20 de ani a unor copiii cu PHS şi s-a raportat că aceasta a fost nefavorabilă la unii dintre pacienţi cu boală moderată iniţial şi cu recuperare completă. Aceşti pacienţi, după 20 de ani de evoluţie, se aflau în diferite stadii de IRC (3,4). Acest model de evoluţie se regăseşte doar într-un singur caz din lotul nostru.

Un alt studiu realizat de un grup de finlandezi, pe un grup de 52 de pacienţi diagnosticaţi cu PHS şi investigaţi 24 de ani mai târziu, relevă că acei pacienţi fără modificări urinare în faza acută au avut o evoluţie, în general, benignă. De asemenea ei relatează că nu există o corelaţie între histologia iniţială şi evoluţia la distanţă. Acei pacienţi cu manifestare iniţială severă au avut un risc şi mai crescut de evoluţie nefavorabilă (5,6,7), ceea ce s-a confirmat şi pe lotul nostru.

Aceste rezultate au fost explicate prin continuarea depunerii în mezangiul glomerular de IgA, chiar dacă faza acută a fost depăşită. O altă explicaţie ar fi legată de susceptibilitatea lor genetică (8).

Din cei 23 de pacienţi (gradele I, II Meadow) care la debut au prezentat doar hematurie microscopică, respectiv protienurie moderată ± hematurie, la 16 dintre ei s-a notat o evoluţie favorabilă pe termen scurt şi la 11 şi o evoluţie favorabilă pe termen lung. Pacienţii doar cu hematurie au prognostic benign, iar cei care au asociat şi proteinurie pot prezenta persistenţa anomaliilor urinare.

În ceea ce priveşte histologia renală , numeroasele studii efectuate relevă faptul că aceasta nu poate fi un factor predictiv pentru persistenţa sechelelor renale şi nici pentru viitoarele recăderi renale. Prezenţa semilunelor în procentaj crescut, a fibrozei interstiţiale şi extinderea depozitelor mezangiale sunt corelate cu risc crescut de IRC (9,10,11). În studiul nostru, prezenţa acestor modificări histologice a determinat evoluţie spre IRC stadiul IV.

Nu există tratament specific pentru NHS. Tipul de tratament aplicat în lotul nostru s-a demonstrat a nu avea un efect semnificativ asupra prognosticului de supravieţuire renală, dar corticoterapia s-a dovedit a avea efect benefic în unele cazuri.

CONCLUZII

1. Pacienţii încadraţi în gradele I şi II de afectare renală, conform clasificării Meadow, au avut o evoluţie favorabilă atât pe termen scurt cât şi pe termen lung, care diferă semnificativ statistic ($p=0,0009$) comparativ cu cea de la pacienţii cu gradele III, IV, V.
2. Histologia renală clasa IV a determinat evoluţia spre IRC, iar majoritatea cazurilor încadrate în clasa III au prezentat în timp doar modificări urinare minime.
3. Pacienţii cu PHS necesită o perioadă de urmărire de cel puţin 10 ani, iar cei cu manifestări de nefrită vor fi evaluaţi periodic pe tot parcursul vieţii.

NOUTĂŢI

Clopidogrelul Şi inhibitorii de pompĂ de protoni

Clopidogrelul este un inhibitor al agregării plachetare utilizat frecvent în asociere cu aspirina la pacienţii cu infarct miocardic, însă are ca efecte adverse creşterea riscului de sângerare gastrointestinală ; în vederea reducerii acestui risc se pot asocia inhibitori de pompă de protoni (IPP). Există mai multe studii care au demonstrat că această asociere poate determina diminuarea efectului antiplachetar al Clopidogrelului, crescând riscul de evenimente trombotice. FDA (Food and Drug Administration) şi EMEA (European Medicine Agency) au tras un semnal de alarmă în privinţa acestei asocieri medicamentoase, recomandând utilizarea de IPP doar la pacienţii cu risc de sângerare gastrointestinală foarte crescut. Un studiu recent pare însă să contrazică aceste temeri. Studiul a inclus 56.406 pacienţi danezi, cu vârste peste 30 ani, internaţi pentru infarct miocardic acut. S-a urmărit rata de apariţie a unui eveniment trombotic (infarct de miocard, atac vascular cerebral), la 30 zile de la infarctul de miocard, pacienţii fiind apoi urmăriţi timp de 1 an. Din totalul pacienţilor 9137 (16,2%) au prezentat evenimente trombotice, 43,8% au primit tratament cu Clopidogrel şi la 27,3% s-a asociat IPP. Studiul a demonstrat că nu au existat diferenţe semnificativ statistice între cele doua loturi de pacienţi, rata de evenimemte trombotice fiind similară (p=0,72). Astfel rezultatele acestui studiu de cohortă demostrează că asocierea dintre Clopidogrel şi un IPP nu creşte suplimentar riscul de evenimente trombotice. (Charlot M, Ahlehoff O et al. Proton pump inhibitors after MI linked to increased risk for adverse cardiovascular outcomes. *Ann Intern Med* 2010 ; 153 (6) : 378-386).

LICHEN PLANUS PIGMENTOSUS INVERSUS IN A 67-YEAR-OLD WOMAN. CASE REPORT (Abstract): Lichen planus pigmentosus inversus (LPPI) is a chronic inflammatory disorder, presenting with brown patches and macules over flexural areas. Due to its histological appearance, LPPI is believed to be a pauci-inflammatory variant of classical lichen planus. Although it is a rare disorder, its epidemiology is variable, case series being reported all over the world. Herein, we report the case of a 67-year-old woman with asymptomatic, brown to purple, macules and patches, distributed over multiple intertriginous areas. Even though current evidence suggests that LPPI is generally resistant to treatment, our patient showed improvement following topical treatment with high-potency corticosteroids. LPPI may be an under-reported disease due to misdiagnosis and it should be considered in the differential diagnosis of pigmentation over flexural areas. **Keywords:** LICHEN PLANUS PIGMENTOSUS INVERSUS, HYPERPIGMENTATION, DERMOSCOPY.

Lichen planus pigmentosus inversus (LPPI) is a rare, chronic inflammatory skin condition, characterized by the appearance of brown patches and macules in intertriginous areas (1). Herein, we report the case of a 67-year-old woman without any relevant personal or family history presenting with LPPI with multiple flexural involvement.

CASE REPORT

A 67-year-old woman presented with a 3-week history of asymptomatic, brown to purple macules and patches, localized over multiple intertriginous areas including axillae, neck, abdominal, and inframammary folds. She did not remember having come into contact with any plants, animals or chemicals. A causal relationship with drugs, sun exposure, or trauma could not be established. Her history was negative for fever, weight loss, and hepatitis B or C virus infection. Patient informed consent was obtained.

Clinical examination revealed multiple brown to purple macules and patches, distributed over the neck, axillary, inframammary, and abdominal folds (fig. 1A-D). The inguinal folds were spared. The macules and patches varied in diameter, from as small as 2-3 mm to several centimeters, some of them coalesced into linear structures (fig. 1A, 1B). The mucosae, hair, and nails were not involved. The patient was otherwise healthy and general clinical examination revealed no abnormalities.

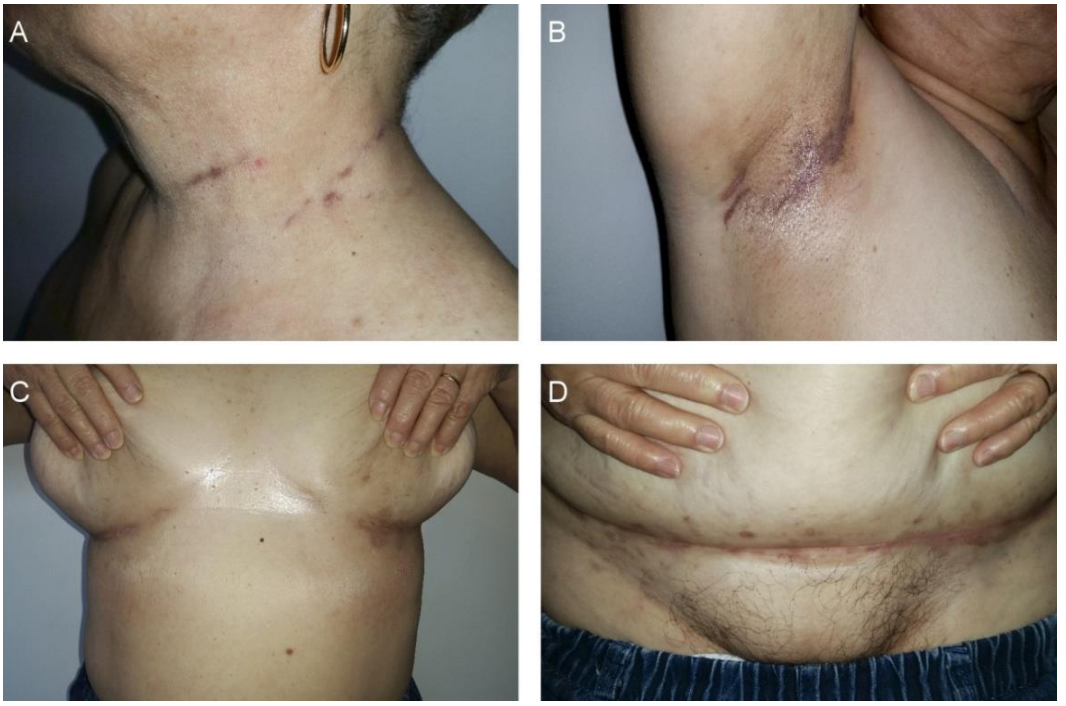

Fig. 1. Clinical images. A-D
Hyperpigmented patches over the neck, axillary, inframammary, and abdominal folds.

Dermoscopic examination of the lesions revealed a mottled white-brown-purple pattern in the absence of a pigmented reticulum (fig. 2B). Homogeneous whitish-pink areas (black arrows) and brown-grey or blue-grey globules and dots (white arrows) could be observed at the periphery of some lesions (fig. 2A). Dermoscopic differential diagnosis included pigmented basal cell carcinoma, pigmented Bowen's disease, pigmented actinic keratosis, and melanoma.

Laboratory evaluation including complete blood cell count, fasting blood sugar levels, liver function tests, serum electrophoresis, serum electrolyte levels, and urinalysis were all within normal limits.

The histopathological examination of a punch biopsy taken from a lesion in the right axilla showed a slightly hyperplastic epidermis with compact hyperkeratosis, hypergranulosis, and vacuolar alteration of the basal layer. The inflammatory infiltrate of lymphocytes, histiocytes, and prominent melanophages in the upper dermis was moderate, and had a characteristic lichenoid disposition (fig. 3A, 3B).

Based on all these clinical, dermoscopic, and histological findings, the patient was diagnosed with LPPI and started on topical high-potency corticosteroids.

Follow-up at one month showed moderate improvement of the neck, axillary and abdominal lesions, and slight improvement of the inframammary ones. At this time, tacrolimus 0.1% ointment was added to the treatment regimen, and at 2-months follow-up all lesion sites showed further improvement (fig. 4A-D).

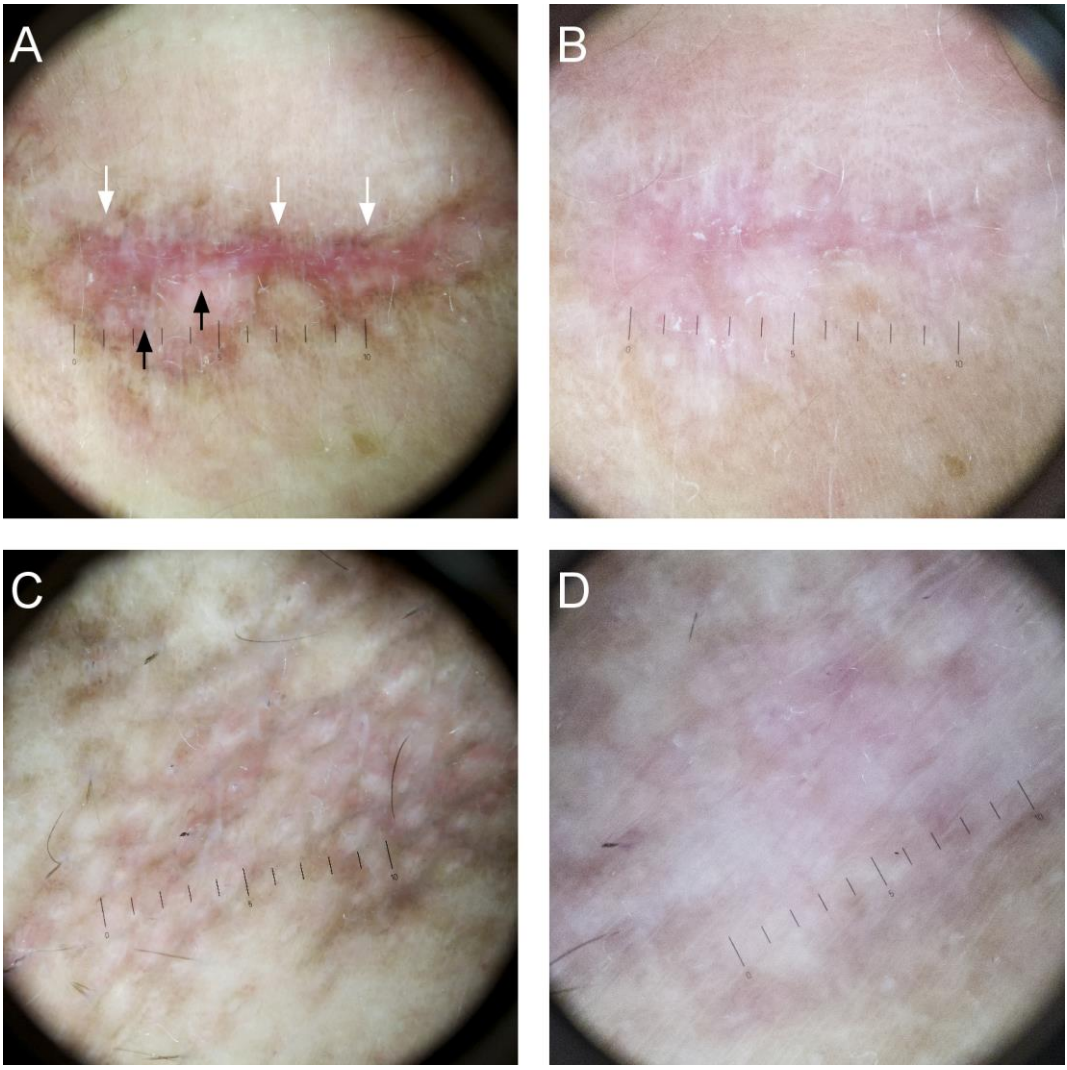

Fig. 2. Dermoscopic features of LPPI.
A - Neck lesion showing homogeneous whitish-pink areas (black arrows) and brown-grey or blue-grey globules and dots (white arrows) towards the periphery;
B - Neck lesion at 2 months follow-up: overall pigmentation is significantly reduced, and globules and dots are absent;
C - Mottled white-brown-purple pattern in the absence of a pigmented reticulum (right axilla);
D - Right axilla lesion at 2 months follow-up shows improvement of the mottled pattern.

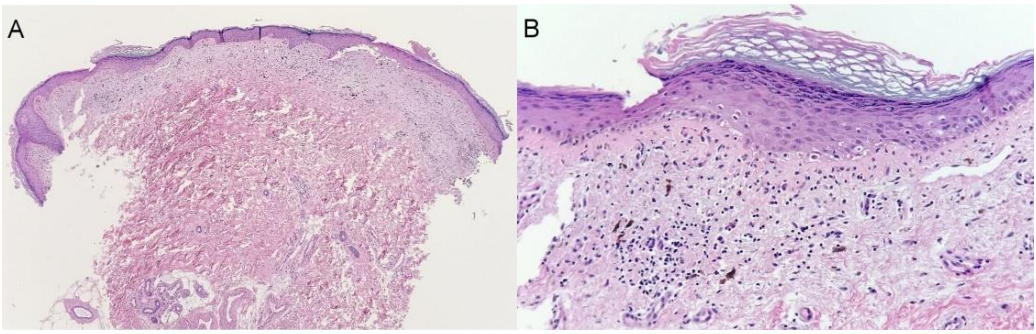

Fig. 3. Histological aspects of LPPI.
A, B Compact hyperkeratosis, hypergranulosis, vacuolar degeneration of the basal layer, moderate upper dermal inflammatory infiltrate showing a characteristic lichenoid disposition (Hematoxylin-Eosin stain, 40x and 400x, respectively).

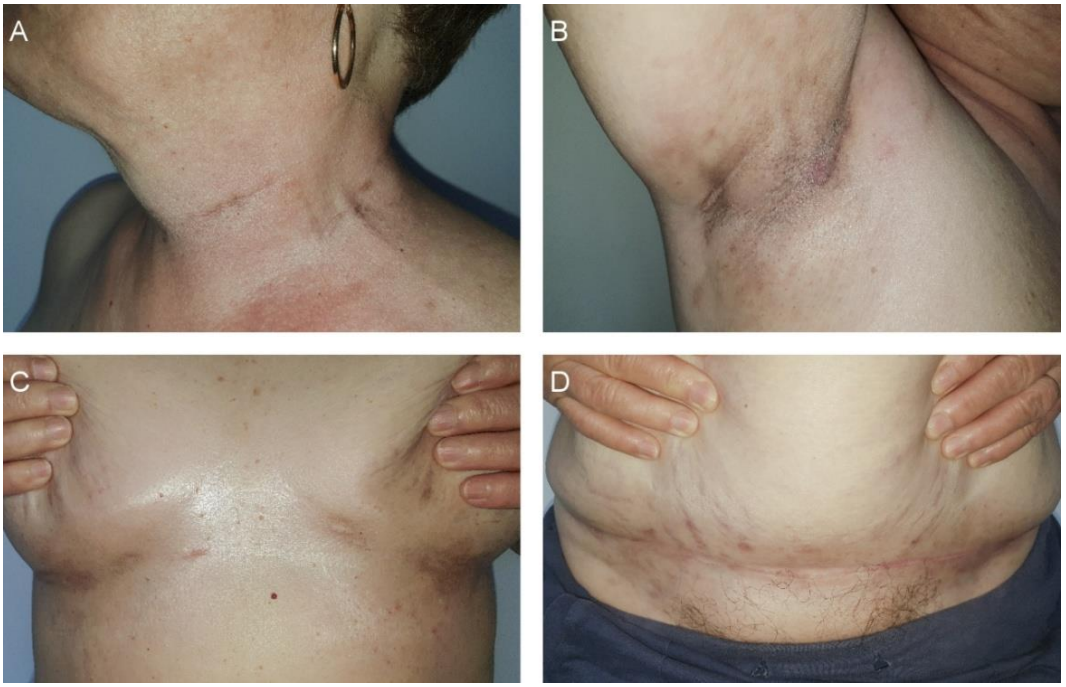

Fig. 4. Clinical images at 2 months follow-up.
A-D - Improvement across all affected areas.

DISCUSSION

The term of lichen planus pigmentosus inversus was coined by Pock *et al* (1) in 2001 after the condition was observed in seven patients with lesions similar to LPP, but distributed in flexural areas. To our knowledge, only 80 cases of LPPI, including the present case, have been reported in the literature until now. LPPI's etiology and physiopathology are poorly under-

stood, but due to histological similarities, many authors have suggested it arises through epidermal flattening of LP lesions in flexural areas (2). The literature confirms the absence of nail, hair and mucosal involvement (3, 4), also observed in our case.

LPPI lesions begin as oval to round macules ultimately coalescing into confluent areas of pigmentation with variable color ranging from slate-blue to steel grey, brown (1, 4), or even purple. Lesion morphology includes linear, reticular, blotchy, blaschkoid or perifollicular patterns (5). The disorder most often affects the axillae, groin, and inframammary folds (5-8), two of these three areas also being affected in our patient. The dermoscopic aspects of LPPI are poorly covered by literature (9-11), and include diffuse brown patches containing grey-brown or grey-blue dots and globules, features similar to those observed in our patient. Histologically, reported cases have mainly described marked pigment incontinence, hydropic degeneration of the basal layer, and a scanty inflammatory infiltrate (1, 7), the regressive lichenoid reaction being in accordance with our findings. The differential diagnosis of LPPI includes LPP, LP actinicus, acanthosis nigricans, pigmented contact dermatitis, and erythema dyschromicum perstans (EDP). A negative history for contact with common allergens rules out pigmented contact dermatitis in this case. Acanthosis nigricans has a more verrucous surface and lacks a lichenoid reaction on histology. EDP affects darker skinned individuals and prefers non-flexural areas of the trunk and limbs, its active lesions showing erythematous borders (1, 7, 12). Reports of diseases associated with LPPI include a single a case of lichen planopilaris (13), one of hepatitis C (14), a drug-induced case by a propolis containing topical agent (15), and an occupational systemic metal sensitization (16). Due to LPPI's reported resistance to treatment including topical (7, 8, 17) and systemic (9) corticosteroids, and topical calcineurin inhibitors (17) some only recommend symptomatic treatment (9, 18), and it has been suggested that a "wait and watch" approach may be the best strategy in LPPI cases (4). Contrary to this, topical treatment with high-potency steroids (clobetasol propionate 0.05%) for only one month led to lesion improvement, our patient continuing to improve constantly after the addition of topical tacrolimus 0.1% ointment.

CONCLUSIONS

Lichen planus pigmentosus inversus seems to be under-reported, probably due to the fact that it is often misdiagnosed. LPPI should, therefore, be considered in the differential diagnosis of cutaneous pigmentation located in flexural areas. More cases are required in order to validate the isolated reports of LPPI's dermoscopic pattern. Even though many authors deem the disorder as "easy to diagnose but hard to treat", our patient showed constant improvement with conventional topical treatments, thus suggesting that some cases of LPPI may be quicker to respond to therapy than others, inevitably leading to questions regarding as to why this may happen.

ACKNOWLEDGEMENTS

Thanks to Dr. Tebeică Tiberiu and "Dr. Leventer Centre" in Bucharest for their help with preparing and interpreting the histopathological sample.

OBSTRUCTIVE SLEEP APNEA PATIENTS VOICE ANALYSIS (Abstract). It is generally considered that obstructive sleep apnea may associate larynx abnormalities – either anatomic or functional in nature ; considering the vocal tract as a series of uniform loss cylindrical pipes the idea of non-invasively exploring this by means of spectral analysis emerged. The aim of our study is to evaluate potential changes in acoustic features of voice in sleep apnea patients as compared to matched controls in order to develop a potential screening test. **Material and method** : Sleep apnea subjects and controls were asked to produce sustained vowels such as "a" and "i" which were recorded and analyzed. Some parameters were estimated – average of fundamental frequency, peak amplitude variation and compared and others are still to be developed. **Key words** : OBSTRUCTIVE SLEEP APNEA, VOICE, FOURIER ANALYSIS

Sleep apnea syndrome is a relatively recently recognized disorder of respiration during sleep. Although a number of factors contribute to its pathogenesis, sleep related changes in ventilatory control, specifically control of upper airway muscles may play a key role in its pathogenesis.

Affected patients have repetitive periods of apnea (i.e., cessation of breathing) that occur during sleep. A period of more than 10 seconds without airflow is generally considered to constitute an apneic episode, and patients with this syndrome often have hundreds of such episodes during the course of a night's sleep. The term *hypopnea* is used to describe a reduction in airflow of 50% or more but without the complete cessation of airflow implied by the term *apnea*. Because episodes of apnea and hypopnea commonly coexist, the broader term *sleep apnea–hypopnea syndrome* is sometimes used. Sleep apnea syndrome is surprisingly common ; estimates suggest a prevalence of 2% to 4% in middle-aged adults. Men are affected more commonly than women, and affected women are typically postmenopausal.

The aim of our study is to evaluate the changes in acoustic features of voice in sleep apnea patients as compared to matched controls in order to develop a potential screening test.

METHOD

Study type : pilot, prospective, monocentric

Subjects

Our study included 40 male subjects divided in two groups : the obstructive sleep apnea group - 20 subjects and the control group - 20 subjects. The groups were matched for age – mean age control 54.6 +/- 5.8 mean ages OSA 52.6+/-10.

Procedure

The subjects were asked to emit two phonemes : [a:] and [e:] for as long as they considered possible with their mouth open and to focus on obtaining a rear resonance. To achieve this purpose a visual incentive

was used. Furthermore subjects were encouraged to perform "at comfortable loudness and pitch" – a situation which according to previous research is linked to a 63-75 dB interval. All recordings were performed in a quite room as a soundproof booth was not available on site.

The subjects were recorded using an electric microphone (frequency range 50--15000 Hz, sensitivity -72dB) at 20-30 cm away from mouth coupled to a Realtek soundcard to a .wav file (48,000 kHz sampling rate). The files were edited and the first and last seconds removed.

Signal analysis was performed using EFx Hist software package and the following parameters were considered for further statistical analysis: close quotient mean (%), mean jitter (%), mean shimmer (%), harmonics to noise ratio (dB), percentile values of the frequency distribution (Hz) and fundamental frequency. For ease mean shimmer and mean jitter values were multiplied by 100. Statistical analysis was performed using SPSS 13.0.

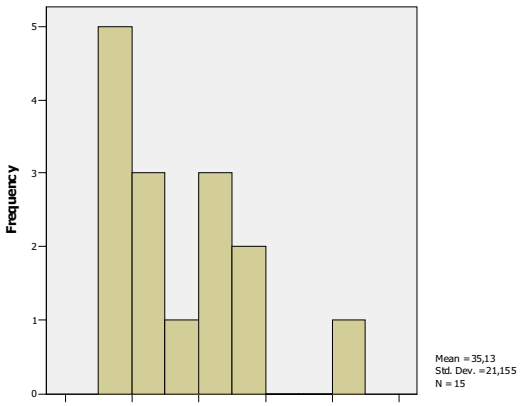

Fig. 1. AHI distribution for OSA group

RESULTS

The OSA subjects had a mean apnea--hipopnea index (AHI) of 35.1+/-21.1 events/hour with a minimum of 14 and a maximum of 86. The distribution of AHI values among OSA group subjects is presented in fig. 1.

Mean voice time was 3.3+/-1.9 seconds with a maximum of 7.5 and a minimum of 0.8 seconds (after editing) for vowel "a" and 3.4+/-2.2 for vowel "i".

As far as fundamental frequency for the two phonemes was concerned - for "a" there was a mean of 131+/-25 Hz in the OSA group and 133+/-25 in the control group; for "i" there was a mean value of 140+/-29 Hz in the OSA group and 148+/-31 Hz in the control group. There were 3 and respectively 4 cases in the OSA and control group for which the fundamental frequency was lower for "i" as compared to "a" – these cases were excluded from further analysis.

There was a statistically significant mean difference as far as the ratio between the two fundamental frequencies was concerned – mean difference 6.5% (95% confidence interval 1.2-11.7%) for p=0.02 (independent samples t-test)

TABLE I
Significant differences for vowel "a" parameters

	Group	N	Mean	Std. Deviation	95% Confidence interval of the difference
Jitter Mean	OSA	15	45.1	13.3	20.0
	Control	17	14.0	16.9	42.2
Shimmer Mean	OSA	15	21.0	10.5	9.3
	Control	17	5.4	6.5	21.9
HNR Mean	OSA	15	17.1	4.4	-5.4
	Control	17	20.1	1.9	-0.5
40% Percentile	OSA	15	204.8	72.0	8.9
					96.3

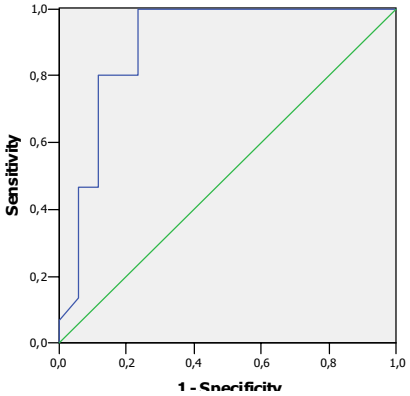

Fig. 2. ROC curve for jitter mean vowel "a"

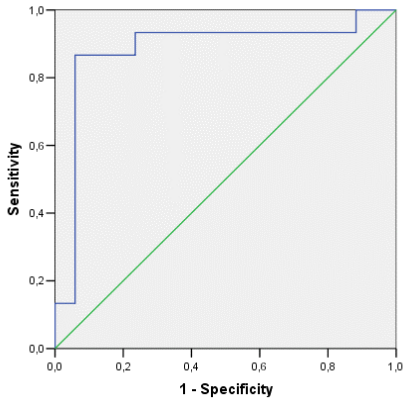

Fig. 3. ROC curve for shimmer mean vowel "a"

As far as the rest of aforementioned parameters are concerned statistically significant between group differences for vowel "a" is presented in table I.

For vowel "i" there were statistically significant differences for jitter mean (mean difference 32.1% ; 95% confidence interval 18.6 – 45.5%) and shimmer mean (mean difference 12.8% ; 95% confidence interval 17.5 – 18.1%).

Using the value of mean jitter for vowel "a" in order to discriminate between groups the following ROC curve (fig. 2) was generated (Area under curve 0.89, asymptotic significance 0.001) ; the cut-off value of 20.2 implies a sensitivity of 86.7% and a specificity of 76.5% but the presence of ties suggests potential bias.

The ROC curve for shimmer mean for vowel "a" is presented in fig. 3 (Area under curve 0.882, asymptotic significance 0.001) and the cutoff value of 10.65 associates a sensitivity of 86.7% and a specificity of 94%.

DISCUSSION

During the last 2 decades, a great deal has been learned about the pathogenesis and the risk factors leading to obstructive sleep apnea syndrome. Normally, inspiration is characterized not only by contraction of the diaphragm, resulting in negative airway pressure, but also by increased activity of a number of upper airway muscles acting to keep the pharynx patent. The genioglossus muscle is particularly important in this regard because it prevents the tongue from falling against the posterior pharyngeal wall and occluding the pharynx.

In patients with obstructive sleep apnea, structural and functional factors often work together to allow the upper airway to close during inspiration. In most patients, an excess of soft tissue in the upper airway, often as a consequence of obesity, compromises the size of the pharyngeal opening. During sleep, particularly rapid eye movement sleep, loss of activity of the upper airway muscles allows inspiratory collapse of the soft tissues and obstruction of the upper airway. Airflow eventually resumes after each episode of obstruction as the patient arouses (although these "micro arousals" often are not evident to the patient), when activity of the upper airway muscles is restored, and when the airway temporarily becomes patent. However, as the patient falls asleep again, inspiratory muscle activity is again lost, and the cycle repeats itself. Because of the importance of structural factors contributing to a small upper airway, patients who are obese (with short, fat necks) or who have a small jaw (micrognathia), a large tongue, or large tonsils are at particular risk for obstructive sleep apnea.

Obstructive sleep apnea commonly occurs

in children of 2-6 years and subsides later as tonsils and adenoid tissue involutes – this fact suggests that larynx and pharynx conformation may play a pathogenic role. Furthermore there are case reports on newly set sleep apnea following vocal cord paralysis (1,2).

Voice analysis has been referred to as a non-invasive and easily implemented tool able to provide useful information complementing standard ENT examinations. To some degree vocal shimmer and jitter may be considered normal but there is a large body of evidence suggesting that increased voice perturbation may be detected in the presence of various larynx conditions (3). These and other vocal determinations are currently used to document and monitor treatment outcomes (4,5).

Since upper airway anatomy seems to be inextricably related to both sleep apnea pathogenesis and vocal characteristics we may infer that some vocal parameters may potentially be used as predictors.

Study limits: The results need to be interpreted considering the group size – rather small given the pilot stage of the study.

Furthermore there was some variability as far as patient performance was involved – the large variations in total voice time may partially explain some of the differences. One explanation for this situation may consist in some associated conditions such restrictive ventilatory disorders (such as obesity-hypoventilation syndrome) which are prone to limit the ability to phonate for longer periods of time; on the other hand some patients reported that they felt awkward performing the requested maneuvers.

There was also some variability concerning the timing of recordings –usually early morning for OSA subjects and late afternoon for control subjects – this may have produced noisier recordings for the first group. Furthermore there is no data on voice parameters variations during the day and we may assume that OSA patients may have experienced a higher stress level under given conditions (night spent in sleep laboratory).

However despite these drawbacks the present results suggest that some vocal changes may occur in sleep apnea patients – either sharing a common cause such as some form of neuropathy and subsequent vocal chord dysfunction either as an effect of this condition. At least in theory there are clinical conditions which predispose to sleep apnea - we may mention hypothyroidism, acromegaly, tonsillitis, adenoiditis, various neurological conditions (focal and systemic), various drugs, tobacco and alcohol all of which usually associate hoarseness.

It is hard to estimate the utility of such parameters as predictors and as screening tests – our OSA subjects had mostly advanced forms of the disease and this situation is usually identified by a skilled physician without further need for screening tests. Given this future study on lower OSA stages subjects is necessary to asses the significance of this approach.

NEW FRONTIERS IN THE HISTOLOGICAL DIAGNOSIS OF DEGENERATIVE AORTOPATHIES MANIFESTED AS AORTIC ANEURYSMS AND DISSECTIONS (Abstract): Nowadays, the histopathological study of surgical specimens is an essential part of the diagnosis of aortic diseases. Despite the increasing clinical-therapeutic complexity of aortic pathology, the criteria for histopathological diagnosis have not been updated for years. In this respect, we applied a consensus document established in 2016 by a staff of pathologists, who improved our knowledge about noninflammatory degenerative aortic lesions by revising, unifying the nomenclature on this topic and bringing terminology and diagnostic criteria up to date. Older terms such as cystic medial necrosis and medionecrosis were replaced by more accurate terms such as mucoid extracellular matrix accumulation, elastic fiber fragmentation and/or loss, and smooth muscle cell nuclei loss. The main aim of the paper is to draw attention on noninflammatory aortopathies, including standard terminology and new grading system, and to define/present histopathological diagnostic criteria applying to these degenerative aortic diseases. The use of this accessible and standardized nomenclature by all general pathologists is important for future diagnosis and research papers as it will allow drawing comparisons between future findings. **Keywords:** AORTIC ANEURYSM, AORTIC DISSECTION, MEDIAL DEGENERATION.

Thoracic aortic aneurysm (TAA) and aortic dissection (AD) are most frequently characterized by degenerative medial lesions**.** Aortic degenerative disease is a common aortic disorder caused by genetic or acquired conditions and manifests as dilated (aneurysm) or dissecting aortic condition. Nowadays, the histopathological (HP) study of surgical specimens is an essential part of the diagnosis of aortic diseases. Medial degeneration (MD) is characterized by smooth muscle cell loss, alteration of elastic fibers and accumulation of the basophilic mucoid pools within the media of the aortic wall. This degenerative process also extends to the elastic components of the adventitial layer. The weakened aortic wall tends to aneurysm formation and dissection (1). Because the meaning of the histopathological terms used to describe MD has become confusing, there is a need for unified nomenclature for the histopathological lesions of the noninflammatory degenerative ascending aorta diseases (2). The application of the consensus document enabled us to assess the extent of lesions by using a new grading scale in order to better and more consistently classify aortic lesions and to

analyze the connection between HP patterns and etiopathogenetic factors.

Histology of the normal ascending aorta

The aorta is a large elastic artery composed of three layers, the intima, media and adventitia, containing some cellular and extracellular components: endothelial cells overlying the intimal layer, smooth muscle cells (SMCs) within the muscular-elastic lamellar unit, elastic fibers, fibrillary extracellular matrix and collagen fibers. The intima is made up of a single layer of endothelial cells overlying loose connective tissue with scarce SMCs and is separated from the media by the internal elastic lamina. Tunica media is organized in morpho functional muscle-elastic lamellar units consisting of bands of elastin filaments with interposed SMCs and separated by collagen fibers and non-fibrillary matrix. The adventitia is composed of loose connective tissue and contains the vasa vasorum, which constitutes the blood supply to the aortic wall, and is separated from the media by the external elastic lamina. This complex organization provides structural substrate elasticity (2).

Histopathological substrate of degenerative aortopathies

Definition and Terminology of Degenerative Aortopathies. The term "degenerative aortic diseases" refers to aortic disorders characterized by cellular and extracellular matrix lesions that are not caused by inflammation, representing the most common clinical expression of thoracic aortic aneurysm (usually located in the ascending aorta) and aortic dissection. The degenerative medial lesions are characterized by fragmentation of elastic fibers, loss of smooth muscle cells, and accumulation of mucoid material (3).

The earliest terminology of degenerative aortic lesions was the classic description of medionecrosis by Erdheim in 1930. For years the concept of "degenerative lesions" replaced "Erdheim's cystic medial necrosis", term used by Erdheim to describe fragmentation of elastic fibers, loss of smooth muscle cells, and accumulation of basophilic ground substance. In 1986, the term medial degeneration replaced the old terminology such as cystic medial necrosis (cyst-like structures containing proteoglycans) and medionecrosis (loss of SMC nuclei), because the observed lesions were neither cystic nor necrotic. Since then, no specific terms have gained full acceptance in describing degenerative medial lesions until 2014. The new terms and definitions were the result of a constant consensus process (of the membership of the Society for Cardiovascular Pathology and the Association for European Cardiovascular Pathology) to create a single unified and consistent set of terms to describe noninflammatory degenerative aortic pathologies (2).

Histopathological Lesions in Aortic Degeneration. From a histological viewpoint, noninflammatory aortic diseases are caused by a great number of disorders involving many histopathological (HP) lesions. These medial degenerative lesions result in medial wall weakening that progresses to aneurysm, dissection, or both (4).

Aortic degenerative lesions include various lesions affecting the medial structural aortic components, either cellular, or extracellular (ECM- extracellular matrix) (1): (a) elastic fibers: thinning with widening of interlamellar space and / or fragmentation and/or loss of elastic fibers; (b) non-fibrillary ECM (mucopolysaccharides or glycosaminoglycans): mucoid material pooling within pseudo cystic spaces variable in size; (c) smooth muscle cells: decrease or loss of SMCs; severe lesions may be accompanied by "laminar medial necrosis" characterized by band–like SMC loss with subsequent elastic fiber collapse; (d) colla-

gen fibers: increase of collagen fibers resulting in substitutive fibrosis.

Eponyms for Selected Histopathological Terms Related to Aortic Medial Degeneration. The Cardiovascular Pathology study group noted that the individual main components of medial degeneration are: MEMA - mucoid extracellular matrix accumulation, EFF/EFL - elastic fiber fragmentation and/or loss, SMCNL - smooth muscle cell nuclei loss, LMC - laminar medial collapse, and MF - medial fibrosis (2).

The New Grading System of Degenerative Lesions. Medial lesions were subclassified and graded (3) according to their distribution and severity, depending on whether they cross multiple lamellar units. The degree of medial degenerative lesions may vary from very little to severe destructive aortic medial alterations (fig.1). Therefore, the grading should be reported as mild/moderate/severe and the distribution should be reported as focal, multifocal, or extensive.

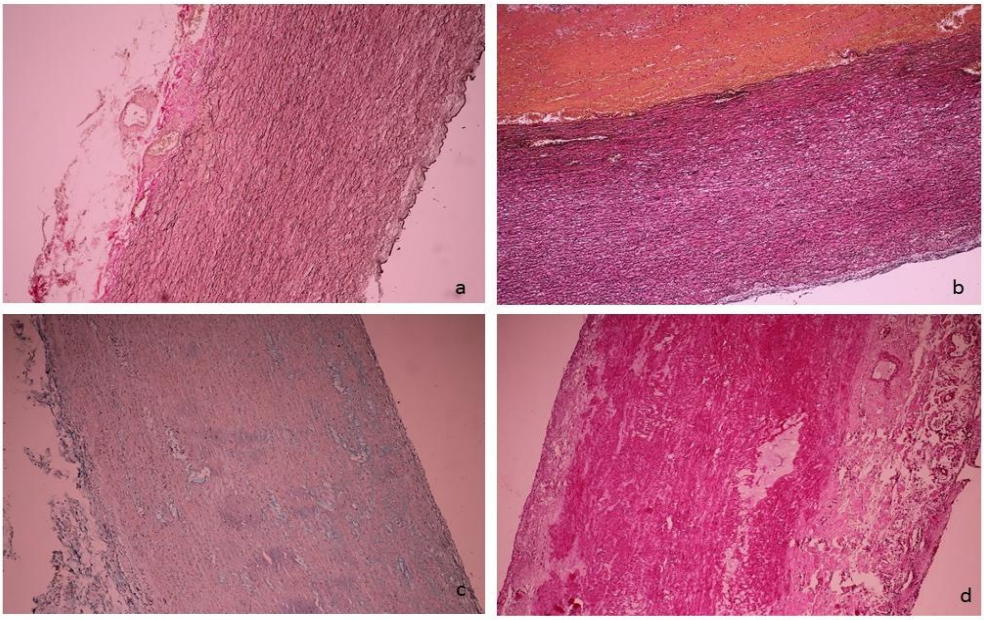

Fig. 1. a) TAA-mild MD and b) AD-mild MD, EVG x10: media with patchy smooth muscle cell loss and mild elastic fiber fragmentation; c) TAA-moderate MD, AB x10: rare smooth muscle cell nuclei loss, multifocal elastic fiber fragmentation and MEMA; d) TAA- severe MD, HE x10: band-like smooth muscle cell loss, severe extensive elastic fiber fragmentation/loss and multifocal trans lamellar MEMA**.**
Abbreviations: AB-Alcian Blue; EVG-Elastic von-Gieson; HE-Hematoxylin-Eosin.

The degree of severity is rated as follows: Mild: lesion involves up to 3 lamellar units; Moderate: lesion involves 4-10 lamellar units; Severe: lesion involves >10 lamellar units. The extent of individual lesions is graded as follows: Absent: the lesion type is not present; Focal: involvement of up to 10% of the media area; Multifocal: multiple areas of involvement of 10–30% of the media area; Extensive: involvement of the media area >30% (4). The application of this grading system in the assessment of all ele-

mentary aortic wall lesions is essential to find new correlations between HP patterns and etiopathogenetic factors.

Etiology

Aortic medial degenerative disease is currently subdivided into two main categories: sporadic and familial degenerative aortopathies (syndromic and non-syndromic) (5).

Degenerative HP lesions may be the consequence of: (a) the normal aging process, in which aortic wall alteration and repair are physiological events; (b) an early and accelerated pathological process in individuals with altered hemodynamic forces (e.g. hypertension, etc.) or in patients with syndromic or nonsyndromic heredofamilial diseases of connective tissue (e.g. Marfan syndrome).

Generally, the causes of thoracic aortic aneurysm (TAA) include inherited syndromes, congenital, atherosclerosis, noninfectious aortitis and infections, and unknown causes (6).

A major cause of noninflammatory thoracic aneurysms is represented by inherited connective tissue disease syndromes, specifically Marfan syndrome (MFS), Loeys-Dietz syndrome (LDS), Ehlers-Danlos syndrome (EDS) and familial thoracic aortic aneurysm and dissection (FTAAD) (11).

Marfan Syndrome. MFS is an autosomal dominant disease, with 25% of patients having no family history. Cardiovascular manifestations of MFS include aortic root dilatation, ascending aortic dilatation, aortic dissections, other sites of aortic aneurysm, and mitral valve prolapsed. The histological feature of aortic aneurysms in MFS is loss of elastic laminas with pooling of proteoglycans, so-called medial degeneration. Histological lesions are also seen to lesser extents in familial non-Marfan aortic dissection and those associated with bicuspid aortic valve (7).

In the absence of any surgical treatment, patients with MFS have a 50% risk of developing aortic dissection during their lifetime. The aortic dilatation observed in MFS is the result of defects in a specific component of the elastic fiber, i.e. fibrillin-1, which is encoded by the *FBN1* gene on chromosome 15 (8).

The clinical diagnosis of Marfan syndrome can be set based on the revised Ghent nosology criteria and confirmed molecularly by analysis of the FBN1 gene. MFS treatment involves the use of beta-blocker and angiotensin-converting enzyme inhibition therapy to achieve reduction of hemodynamic stress and delay the progression of arterial dilatation. When critical dilatation of the aorta occurs, with significant risk for aortic dissection or rupture, aortic root replacement surgery is performed (9).

Loeys-Dietz syndrome. LDS is an autosomal dominant Marfan-like connective tissue disorder that is an increasingly recognized cause of thoracic aortic aneurysm. It results from genetic mutations in the transforming growth factor beta receptors 1 and 2 (TGFBR1 and TGFBR2). From the histological point of view, there is diffuse medial degeneration, which may be subtle (10). The cardiovascular manifestations in LDS are arterial tortuosity with aneurysms and dissections. LDS has an earlier onset than MFS, with recommendations for prophylactic aortic root replacement at younger ages and with smaller aortic dimensions (11).

Ehlers-Danlos syndrome. Type IV EDS (vascular type) is due to defects in type III procollagen (COL3A1) (19). It causes vascular fragility with aneurysm formation, rupture, and dissections, with possible life-threatening consequences. When the aorta is involved, it may lead to multiple rupture, usually affecting normal-caliber artery. Patients with type IV EDS may also have TAAs (12).

The diagnosis of type IV EDS is based on physical examination, biochemical analysis of the collagens on cultured skin fibroblasts and molecular analysis of the

COL3A1 gene. No current etiological treatment is available, and management focuses on symptomatic control.

Familial thoracic aortic aneurysm and dissection. FTAAD is a rare condition that affects a subgroup of patients with HP medial degenerative disease. In people affected by this condition, the thoracic aorta may become weakened, stretched and/or enlarged. This can lead to a sudden tear of the inner wall of the aorta that allows blood to dissect the aortic wall. These aortic abnormalities can be life-threatening due to aortic rupture (13).

Idiopathic, noninflammatory aneurysms are also associated with congenital conditions (bicuspid aortic valve) and acquired conditions (hypertension).

Bicuspid Aortic Valve with Ascending Aortic Aneurysm. From a genetic viewpoint, little is known about bicuspid aortic valve (BAV). BAV is a common congenital cardiac defect that affects 1% to 2% of the general population, who run a risk of proximal aortic aneurysms and dissections. Unicuspidal aortic valve is associated with TAA at an even higher rate.

The cardiac manifestations of the BAV disease, which becomes manifest in most patients during the course of their lifetimes, are isolated aortic regurgitation, isolated ascending aortic aneurysm, aortic regurgitation associated with aortic aneurysm, isolated aortic stenosis, and aortic stenosis with aneurysm (14).

Approximately 25% of patients with TAAs have no known cause or association. The major association is systemic hypertension.

Hypertension. Varying degrees of degeneration can be seen in patients without familial syndromes, as an acquired form, usually associated with hypertension (HTA).

Differences between these degenerative HP lesions in various primary and secondary conditions, including aging process, are quantitative rather than qualitative. The involvement of cell cytoskeleton and extracellular matrix components is at the basis of the main degenerative histopathological elementary lesions (15).

Other Rare Causes. *Aortic atherosclerosis* (a) appears to play a major role in aortic arch, descending thoracic and abdominal aorta disease. Atherosclerosis can result in aortic wall weakening, making it prone to aneurysm formation or dissection. *Inflammatory aortic disorders* (b) represent a third broad category of predisposing factors causing aortic diseases. These occur in the context of isolated or systemic disorders such as inflammatory vasculitis. They include infectious and non-infectious causes (8). *Traumatic aortic dissection*(c) often occurs at the level of the left subclavian artery with formation of a chronic pseudoaneurysm (16).

Clinical manifestations of degenerative aortopathy

Degenerative changes of the aortic media and consequent weakening of the aortic wall lead to aneurysm formation and dissection. Aneurysms are less common in the thoracic aorta, where they are more prone to dissection.

Thoracic Aortic Normal Anatomy. Anatomically, the thoracic aorta is divided into subcomponents. The thoracic aorta consists of the aortic root, the ascending aorta (with an average diameter of 3 cm), the arch, and the descending thoracic aorta, with an average diameter of 2.5 cm.

Aortic Aneurysm. An aneurysm is defined as a dilatation at least 50% above the normal diameter of an artery. In the thoracic aorta, a diameter of 3 cm or greater is generally considered aneurysmal. Usually, the term aortic aneurysm refers to an aortic dilatation of over 5cm in diameter. The growth of aneurysm may be indolent. Serial imaging studies can show a slow growth rate (about 1 mm yearly) until the diameter is

about 5 cm, at which time it may be more rapid (17).

TAAs can involve the aortic root, ascending aorta, arch, descending aorta, or a combination of these locations. The combination of aortic root dilatation and ascending aneurysm is termed "annuloaortic ectasia".

Clinically, a large percentage of patients with noninflammatory aortic disorders come in with asymptomatic thoracic aortic aneurysms. These thoracic aneurysms are usually found incidentally by imaging studies. Sometimes, after unexpected rupture, the pathologist may find them during the autopsy. Usually, symptoms are related to aortic insufficiency (aneurysms involving the aortic root or ascending aorta), dissection, or rupture (18).

Aortic Dissection. Aortic dissections are frequently superimposed on noninflammatory TAAs; these aneurysms are named "dissecting aneurysms". Anyway, aortic dissections may occur with medial degeneration in the absence of a pre-existing aneurysm.

AD is defined as separation of the layers within the aortic wall. It is caused by splitting of the aortic wall within the external media, which results in the formation of an aortic false lumen that runs along a true lumen. The hallmark of classic aortic dissection is an intimal tear, with blood entering the aortic wall and formation of an intimal flap protruding within the false lumen of the aortic wall (19).

Aortic dissection, representing the most threatening acute aortic syndrome, includes other dissection variants such as intramural hematomas, penetrating aortic ulcers (especially in abdominal aorta) and symptomatic aneurysms (18). Intramural hematoma (IH) and penetrating aortic ulcer (PAU) differ from classic dissection by the absence of an intimal flap. IH is a non-communicating blood collection in the aortic wall with blood lumen. IH can result in primary rupture of the vasa vasorum. Unlike a true dissection, there is no loss of intimal continuity, no entry tear, and thus no intimal flap. Recent advances in diagnostic imaging can reveal these entities (19). PAU develops when an atheromatous plaque erodes into the aortic media. Depending on how far into the aortic wall the plaque erosion occurs, there can result an intramural hematoma or even complete aortic rupture. This lesion is more commonly encountered within the abdominal aorta (20). Dissections occurring in younger patients (younger than 40 years) typically occur in the context of connective tissue disorders such as Marfan syndrome, Loeys-Dietz, congenital bicuspid aortic valve, and previous aortic surgery (14, 17).

In patients with chronic aortic dissection (present for >2 weeks) surviving the period of increased mortality, the aortas often dilate and are at higher risk for aneurysm formation due to reduced elasticity of the thinner aortic wall remaining after dissection. A rare type of AD is iatrogenic aortic dissections. Aortic cross-clamping or cannulation during cardiac surgery and angiographic catheters can disrupt the aortic intima resulting in iatrogenic dissections anywhere along the aorta's course. These dissections are usually diagnosed and treated at the time of surgery (21).

CONCLUSIONS

The goal of this paper is to draw attention on several noninflammatory aortic disorders which can be related to TAA and AD in young and adult patients. While some are more prevalent than others, it is clear that the severity of the clinical spectrum of many of these disorders is highly variable. This would be the cause of underdiagnosing this aortopathy.

In this respect, we would like to point out the importance of a good familial history, HP examination and genetic screening. Usually, features of acquired MD in the aging aorta bear close resemblance to medi-

al changes in the genetic syndrome, while in the case of genetic syndromes, these degenerative changes are more extensive, and they occur at an earlier age.

THE INFLUENCE OF DIABETES ON GLAUCOMA PROGRESSION - PROSPECTIVE STUDY (Abstract): Purpose of the study: To outline the influence of diabetes on the progression of glaucoma. **Material and methods:** The study (prospective, case-control) analyzed the data from 102 patients with glaucoma admitted to the Clinic I Ophthalmology of "Sf. Spiridon" County Clinical Emergency Hospital from Iasi, between October 2011 and November 2015, divided into two study groups, depending on the presence of diabetes, as follows: First group 51 patients with Diabetes and Glaucoma (study group) and Group II 51 patients with glaucoma, without Diabetes (control group). In all patients, the following parameters were recorded: VA (visual acuity), IOP (intraocular pressure), visual field progression, corneal thickness, and fundus appearance, where the presence of DR (diabetic retinopathy), its progression and form when it existed, as well as optic disc appearance. Also, it was noted: the duration of glaucoma, diabetes and the type and quantity of antiglaucoma and antidiabetic medications used and the number of VF examinations (visual field) and OCT (ocular coherence tomography), glycemic and HbA1c values. **Results:** At the end of the study, for the patients in group I there was a significantly decrease visual acuity in patients with severe glaucoma ($p = 0.001$). The mean IOP values did not show statistically significant differences compared to the evolution of glaucoma. At the end of the study, the C/D ratio (cup / disc) was significantly higher in patients in group II ($p = 0.017$). The presence of Diabetes had a negative impact on RNFL (retinal nerve fiber layer) among patients with an advanced form of glaucoma. For the patients in the study group, who had a high blood glucose level, it was noted: a significant decrease in the mean IOP, a significant decrease PSD (pattern deviation) and significant decrease mean MD (mean deviation). **Conclusions:** In our study, the data from the analysis of VF, OCT and clinical examination parameters indicate an unfavorable progression of glaucoma among diabetic patients compared to those without. **Keywords:** POAG, NTG, OCT, MD, PSD, DIABETES.

Glaucoma and diabetes are two chronic conditions that have an increased prevalence among the population over 40 years old. Both diabetes and glaucoma lead to irreversible vision loss after a period of evolution. Numerous studies have attempted to find possible associations between diabetes and primitive open-angle glaucoma (POAG) with conflicting results.

MATERIAL AND METHODS

The study (prospective, case-control)

analyzed data from 102 glaucoma patients admitted to Clinic I of Ophthalmology at "Sf. Spiridon" County Clinical Emergency Hospital from Iasi, between October 2011 and November 2015, divided into two study groups, depending on the presence of diabetes, as follows:

- Group I - 51 patients with diabetes and glaucoma (study group);
- Group II - 51 patients with glaucoma without diabetes (control group).

Inclusion and exclusion criteria. The inclusion criteria were: POAG or NTG (normal tension glaucoma) for the control group and the study group with diabetic patients. Patients with other types of glaucoma (pseudo-exfoliative, pigmentary, cortisonic, neovascular, and narrow-angle primitives) were excluded from the study. Patients with age-related cataracts were also excluded, whose visual acuity (VA) was very low.

In all patients, the following parameters were recorded: VA, decrease in IOP (with Goldmann Aplanotonometer), perimetric evolution (MD and PSD recording by *Humphrey Field Analyzer II Zeiss Automatic Perimeter*), Corneal Thickness and fundus examination with the *Volk 78D* lens. The presence of DR, its progression and its form was noted, but also the aspect of the optic disc. It was also noted: duration of glaucoma and diabetes, the type of diabetes (1, 2 and mixed), number and type of antiglaucoma and antidiabetics medication, the number of examinations VF and OCT. Inconclusive OCT and VF examinations were excluded from the analysis. For all patients, glycemic and glycosylated hemoglobin (HbA1c) values were recorded to confirm or discontinue the diabetic status of the patients in both groups. At the same time, in the clinical examination, the anterior chamber angle was analyzed by gonioscopy for the correct fit of the glaucoma. OCT examinations were performed at the *OFTAPROF Clinic* with Cirrus HD-OCT Zeiss using the Optic Disc Cube 200 x 200 protocol. The following were recorded: mean retinal nerve layer thickness (RNFL), RNFL symmetry, Neuroretinal rim, optic disc area, mean C/D ratio, vertical C/D ratio, volume of the optic disc cup.

Another necessary condition for participation in the study was to have VF and OCT examinations at intervals of at least one year between the initial and final assessment. The study only analyzed the data from the most affected eye of the two.

All patients enrolled in the study agreed to participate, signing an informed consent in accordance with the Helsinki Declaration (June 1964).

The criteria for the diagnosis of NTG and POAG were age greater than 35 years, normal intraocular pressure (IOP) or more than 21 mmHg without treatment, open anterior chamber angle, damage to the optic nerve characteristic of glaucoma (ratio C/D> 0.5) , VF defects.

Evaluation of DR changes was performed with the *Volk* lens and retinal photography at the *Fundus Camera Zeiss*, monitoring all quadrants. Progression was defined by any newly developed clinical element that led to a more severe form.

In the case of the study group, only 21 of the 51 patients performed at least one second OCT exam. For the study group, when analyzing the OCT parameters, only the data from the 21 patients was included.

Statistical analysis. With a sampling error of 9.5%, the study represents a representative sample. The data was systematized and centralized into a *SPSS version 18.0* database and processed with the fol-

lowing statistical functions: *ANOVA* test, *t-Student* test, *F (ANOVA)* test, correlation coefficient *Pearson* (r), χ^2 test, *Kruskal-Wallis* correlation, linear regression, multiple regression, *ROC* curve.

RESULTS

Visual acuity: At the beginning of the study, visual acuity was significantly higher in patients from Group II (p = 0.015). At the end of the study, visual acuity significantly decreased in patients from Group I in those with severe glaucoma (p = 0.001).

The mean values of the IOP: did not show statistically significant differences depending on the evolution of glaucoma.

C/D. At the onset of the study, the C/D ratio was significantly higher in patients in group II (p = 0.017). At the end of the study, the C/D ratio was slightly lower in patients in group I (p = 0.680).

After analyzing the initial and final C/D report in both batches, we conclude that the tendency was equalization that occurred mainly through "recovery" (which translates into growth) of the C/D in the study group. In other words, in the diabetic group, the increase in C/D ratio is more pronounced**.**

RNFL. At the start of the study, RNFL was significantly lower in group II patients with moderate and severe forms of glaucoma (p = 0.043). At the end of the study, in Group I RNFL significantly decreased in patients with severe glaucoma (p = 0.001). This development indicates that the presence of diabetes had a negative impact on RNFL among patients with advanced forms of glaucoma (fig.1).

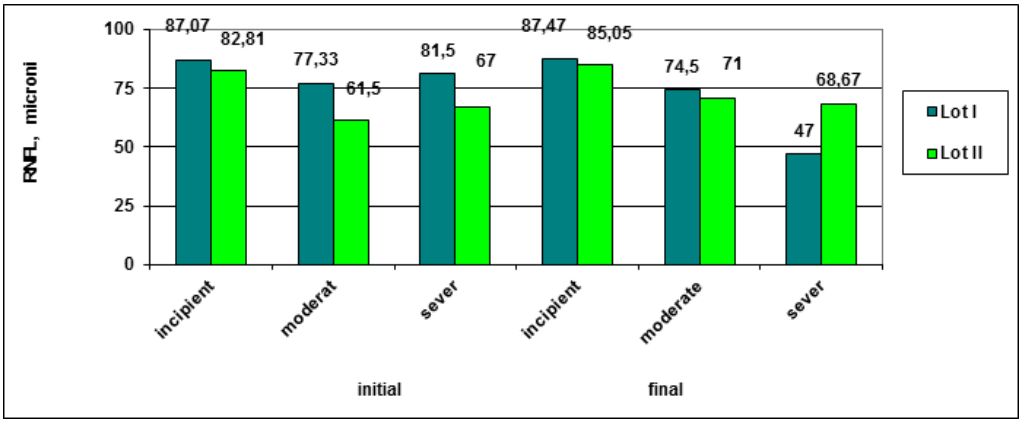

Fig. 1. Average values of RNFL by study group according to MD classification

RNFL Symmetry. At the start of the study, RNFL symmetry was significantly lower in Group I patients with moderate glaucoma and in Group II patients with severe glaucoma (p = 0.001). At the end of the study, there were no statistically significant differences, according to glaucoma development, of the mean values between the analyzed groups (p = 0.546).

Neuroretinal rim. At the start of the study, mean values of the neuroretinal rim were significantly lower in patients from Group II with moderate and severe glaucoma (p = 0.025).

The size of the disc was not statistically significant in the evolution of glaucoma.

Mean C/D. At the start of the study, the mean C/D was significantly higher in pa-

tients with moderate and severe glaucoma in Group II (p = 0.045). At the end of the study, the mean C/D was lower in patients from the first group with severe glaucoma (p = 0.042).

Cup-Disc Volume. At the start of the study, the cup-disc volume was significantly higher in patients with moderate and severe glaucoma from Group II (p= 0.031). At the end of the study, the cup volume was lower in patients from Group I with incipient glaucoma (p = 0.05).

HbA1c. At the start of the study, patients from Group I had a significantly higher level of IOP (19.90 *vs.* 17.30 mmHg; p = 0.029), a difference that was maintained until the end of the study in patients with HbA1c ≥ 7% (16.38 *vs.* 15.30 mmHg, p = 0.001). This would suggest that elevated levels of HbA1c would maintain elevated IOP values, although no correlation between the mean values of the two was found across the study group (tab.1).

TABLE I

Evolution of markers by HbA1c level at patients in the study group

Marker	Initial			Final			$p_{i\ vs\ f}$ HbA1c > 7%
	HbA1c ≥7%	HbA1c <7%	p	HbA1c ≥7%	HbA1c <7%	p	
Visual field							
VA	0.75±0.26	0.84±0.18	0.158	0.75±0.18	0.81±0.24	0.352	0.958
IOP	19.90±5.12	17.30±3.15	**0.029**	16.38±3.61	15.30±2.35	0.201	**0.001**
C/D	0.56±0.19	0.58±0.19	0.668	0.58±0.17	0.57±0.18	0.848	0.495
PSD	2.65±2.27	3.12±2.86	0.537	4.45±3.58	3.64±3.40	0.421	**0.002**
MD	-1.48±3.92	-5.48±3.81	**0.005**	-6.20±7.75	-3.88±6.70	0.258	**0.008**
OCT							
RNFL	83.71±15.40	86.73±13.13	0.455	85.60±14.73	84.45±15.19	0.863	0.199
Symmetry RNFL	69.43±29.22	80.36±8.51	**0.046**	82.50±7.77	77.36±9.65	0.198	**0.040**
Neuroretinian area	1.15±0.23	1.17±0.28	0.762	1.15±0.24	1.10±0.32	0.745	0.885
Disc area	2.04±0.39	2.08±0.41	0.727	1.95±0.22	2.26±0.54	0.105	0.054
C/D average	0.64±0.11	0.64±0.12	0.962	0.63±0.12	0.70±0.10	0.145	0.940
Vertical C/D	0.63±0.12	0.63±0.11	0.959	0.60±0.12	0.67±0.08	0.109	0.891
C/D volume	0.30±0.15	0.38±0.29	0.254	0.26±0.19	0.52±0.37	0.061	0.795

At the end of the study, there was a significant increase in the mean PSD (4.45 *vs.* 3.64; p = 0.002). In patients with an HbA1c level ≥7%, a significant decrease in MD was noted at the end of the study (-6.20 *vs.*-3.88, p = 0.008). As above, elevated levels of glycosylated hemoglobin would induce more severe impairment of visual function monitored by VF examination (tab. I).

RNFL symmetry was significantly lower at the beginning of the study in patients with HbA1c levels ≥ 7% (69.43 *vs.* 80.36; p

= 0.046), increasing significantly by the end of the study (82.50 *vs.* 77.36; p = 0.04).

Blood sugar. At the start of the study, patients in the study group (with diabetes and glaucoma) showed a significantly lower VA level (75% *vs.* 91%, p = 0.019), which is maintained until the end of the study (72% *vs.* 85 %, p = 0.03), and RNFL was significantly lower in the beginning (83.08 *vs.* 91.27; p = 0.05), with the difference decreasing by the end of the study (82.62 *vs.* 88.88, p = 0.177). In patients from the study group who had a high blood sugar levels and remained above the baseline until the end of the study, the following evolution of the biological markers was noted:

- mean IOP values significantly decrease from 18.28 ± 4.76 mmHg to 15.44 ± 3.12 mmHg (p = 0.001);
- PSD significantly increases from 2.91 ± 2.03 to 3.86 ± 3.14 (p = 0.042);
- mean MD significantly decreases from -3.83 ± 7.52 to -4.99 ± 7.87 (p = 0.05).

DISCUSSION

The two batches were comparable in terms of glaucoma stage and time since diagnosis.

Analyzing the number of VFs and OCTs performed by patients, there was noted a more in-depth examination for those diagnosed with NTG and a slightly larger number of examinations of patients with diabetes. These aspects are due to the increased need for the clinician to obtain diagnostic data in the absence abnormal IOP values for patients with NTG, but also due to patients increased ocular comorbidities in diabetic patients, which is also reflected in multiple studies in the literature (1-6).

The presence of diabetes did not correlate with the thickness of the cornea or with the IOP values, both of which lead to the conclusion that if diabetes influences in some way the evolution of glaucoma, this does not happen through a biomechanical mechanism.

There was an indirect correlation of low intensity between C/D values with glycemic status (HbA1c and glucose values). Over the course of the study high values of diabetic parameters (blood sugar or HbA1c) can be correlated with favorable prognostic factors of glaucoma such as low C/D ratio. Looking at the dynamics and comparing the tendency of this correlation between the final and the initial moment, it is noticed that over time, this "favorable" effect of diabetes on glaucoma is no longer as pronounced. Furthermore, it should be stated that higher blood sugar levels have been recorded at baseline, compared to the end of the study and the fact that natural evolution of glaucoma results in increasing the C/D ratio value. In fact, this parameter had a similar evolution in both groups.

Analyzing each type of glaucoma (POAG and NTG) in the evolution of the C/D ratio it is observed that NTG recorded the highest values. Besides the fact that the assessment of NTG is subjective, related to the experience and behavior of each clinician, there is a tendency (at least at the time of diagnosis) to underestimate this ratio under normal IOP values as defined by this pathology. Because of that the diagnosis is decided later, in more advanced stages, where we encounter higher C/D values. This is most likely to be found in the “favorable” improvement in the assessment in people with NTG in the study group (C/D: 0.6 initially versus 0.56 final). In these patients, the presence of comorbidity may influence the examiner's decision. All this information was not sta-

tistically significant. A longer follow-up could provide new clues in this evaluation.

The different correlation of the C/D and VA ratio in the two groups (positive for the glaucoma and diabetes group and negative for the glaucoma group only) is based on low AV rates in patients with diabetes. Most studies assess AV in diabetes in advanced forms with retinal changes. In the early stages (on patients where DR is not significant, similar to the present study), VA values have different behaviors across other studies. In a study from 2000 of two similar demographic groups (age and gender) of 385 patients, there was a low VA value among diabetes patients compared to the control group: 40% *vs.* 31% (7).

On the other hand, in a Swedish study published in 2007, there is no difference in VA between two groups: the study group made up of people in a well-defined population area diagnosed with type 2 diabetes compared to a similar control group, without diabetes. One person blinded because of DR, however, the main cause of decreased vision was age-related macular degeneration in both groups (8).

Discussion based on visual field data

Analyzing the data obtained from the VF examinations, there is a decrease in the MD values in both groups (study and control) for patients diagnosed with NTG and a trend of PSD increase (highlighted by an important statistical correlation: $p = 0.004$) for patients in the study group. This last aspect, even if the values have not reached the pathological area, raises questions about what would have happened if the study period would have been longer.

The absence of correlation between intraocular pressure values and MD and PSD values in both groups may have two causes: Progression prevention by effective antiglaucoma treatment and / or reduce follow up period for the study (2.38 ± 1.20 years study group, respectively 2.26 ± 1.0 years the control group). In addition, this synchronic behavior of the two VF parameters is also reinforced by the statistically strong indirect (normal) correlation obtained between these values throughout the study and within each group ($p = 0.001$).

Analyzing the evolution of the two VF functional parameters MD and PSD, we observe a lower number of VF examinations among the patients in the study group compared to those in the control group:

- Mean differences of the final MD - initially recorded a more significant decrease among people with diabetes compared to those without -1 dB and -0.54 dB ($p = 0.701$);
- Mean PSD differences - initially recorded a more significant increase among people with diabetes compared to those without: + 1dB *vs.* +0.22 dB ($p = 0.041$).

It would also be interesting to divide each group according to the MD classification and then to study the evolution of this parameter over time and to compare similar subgroups on each side. For example: Advanced subgroup (<-12 dB) in study group (diabetes and glaucoma) versus advanced subgroup of control group (glaucoma only). However, in order to have statistical relevance, each subgroup formed within the two groups should have been numerically important, which is, unfortunately, impossible in the present study.

Discussion based on OCT data

The results following the analysis of the OCT data (structural assessment) were conflicting. There was noted an increase in RNFL thickness in both groups, although

the natural tendency is thinning even in healthy subjects. However, comparing the two groups against each other, the increase in RNFL was less in patients with Diabetes.

RNFL Symmetry registered a decline among the study group. This finding, however, was not statistically significant.

The mean C/D value increased by the end of the study in both groups. However, this increase was more important in the study group and had statistically significance ($p = 0.044$). This would suggest the fact that the presence of diabetes has an unfavorable effect on the development of glaucoma disease. The same conclusion can be drawn if we look at the more pronounced increase of the vertical C/D in the group of patients with diabetes and glaucoma. The statistical correlation is, however, weaker.

The volume of the optic disc had increased significantly more among NTG patients in both groups.

On the other hand, diabetic parameters (HbA1c and glycemia) correlated negatively with almost all OCT values: RNFL symmetry, mean C/D, vertical C/D, cup volume. In conclusion, elevated levels of HbA1c and glucose were associated with "more favorable values" of OCT examinations.

From the obtained results, we can observe a significant indications suggesting the negative impact of diabetes on the development of glaucoma. This comes from the analysis of functional data obtained from clinical examinations and VF examination but also partly from the structural analysis, which was revealed by OCT examinations. These findings are in line with the meta-analysis published in 2004 by the team led by Bonovas S., which states that diabetes is a risk factor for POAG (4).

Even though it wasn't statistically significant, a generally positive correlation between IOP and diabetic parameters (HbA1c and glycemia) was observed. This is similar to the results published by Zhao D et al. in 2015. They found that for each increase in blood glucose of 10 mg/dl there was an increase in IOP by a mean of 0.09 mmHg6. However, the data from the study may have been influenced by the introduction of antiglaucoma medication, which was meant to control or even decrease the IOP.

In contrast, the data indicating a protective role that diabetes would have on glaucoma comes mainly from the analysis of intragroup information obtained in the study group (with diabetes and glaucoma), specifically that elevated levels of diabetic parameters were associated with more favorable aspects of glaucoma.

Analyzing the OCT data, an improvement of the RNFL thickness was generally observed in the two groups. This can be explained by small batches and the short period of the study, which could leave room for possible errors and limitations of this type of investigation (OCT). At the same time, as Primus S. and colleagues suggest, this OCT structural objective improvement may be due to the improvement of retinal vascular flow in the early stages of diabetes (9), but also due to the decrease in the mean values of IOP.

Existence of diabetes did not correlate with corneal thickness or IOP values, both of which lead to the conclusion that if diabetes influences in some way the evolution of glaucomatous disease this does not happen through a biomechanical mechanism. This is in contrast to the data published by Zhao D *et al.* which reveals that hyperglycemia could induce an osmotic gradient that would attract an excess of aqueous

humor in the anterior chamber, which could affect trabecular meshwork function and that diabetes may increase the stiffness and central thickness of the cornea (6).

Diabetes negative role. Among the results that suggested a negative influence of diabetes on glaucomatous disease progression, we mention:

- The mean reduction in MD was more significant in patients with diabetes compared to those in the control group: -1 dB *vs.* -0.54 dB (p = 0.701).

- PSD values increased more among patients with diabetes than those with glaucoma alone: +1dB *vs.* +0.22 dB (p= 0.041).

- RNFL symmetry also recorded deterioration among the group: diabetes and glaucoma (p = 0.758).

- increase in mean C/D was more important in the presence of diabetes (p = 0.044).

- The same behavior was also encountered in the evolution of vertical C/D values (p = 0.164). In the literature, Mwanza JC *et al.* emphasizes that for the diagnosis of glaucomatous disease, data are related to the neuroretinal rim area and the vertical cup/disc ratio (10).

The presence of diabetes had a negative impact on RNFL in patients with advanced forms of glaucoma (p = 0.001).

Diabetes protective role. Among the results suggesting a protective role of diabetes on the development of glaucoma were all correlations between blood glucose levels and HbA1c and structural measurements determined by OCT examination: RNFL symmetry, mean C/D, vertical C/D, cup volume. Almost without exception, elevated values of these parameters correlated with less affected structural measurements on the OCT examination.

The study also has limits. The follow-up period was short: 2.38 years of follow-up through VF examinations in the study group and 2.26 in the control group, respectively 1.86 years between final and initial OCT examination in the study group and 1.82 in the control group. Consequently, the number of VF and OCT examinations was rather low, especially the OCTs. The number of patients was low, especially those who underwent OCT examinations in the study group. The majority of patients came from the urban area, showing that at least in rural areas these two diseases remain undiagnosed and unexamined.

It would have been interesting to divide the groups either according, to the stage of glaucoma evolution (early, moderate and severe) in order to assess the impact of diabetes at each of these stages or to the degree of diabetic control (normal, controlled, moderately controlled or uncontrolled). It is expected that, in order to have a statistically significant data with subgroups of this kind, a larger number of patients is required. This is more likely with multicenter studies.

Also, considering the vascular physio pathological mechanisms that appear to be involved in the pathology of the two diseases (diabetes and POAG), it would have been interesting to analyze the ocular perfusion pressure in this study as well.

In order to achieve more accurate results, a longer study period is needed, which considers the chronic nature of the pathologies involved.

CONCLUSIONS

In our study, data from the VF, OCT, and Clinical Examination Parameters analysis indicate an unfavorable progression of glaucoma among diabetic patients compared to those without. This is based

on a more significant degradation of these parameters within the study group compared to the control group. In contrast, data suggesting a favorable impact of diabetes was obtained only inside the study group and showed negative correlation between diabetic parameters (glycemic and glycosylated hemoglobin) and the clinical and paraclinical parameters of glaucoma. However, this information was not supported by statistically significant value.

Patients in the study mostly came from urban areas. This highlights the low addressability and difficult access of people from rural areas to health services. Consequently, both glaucoma and diabetes remain underdiagnosed and underestimated if not among the entire population, at least among those in rural areas.

Longer follow-up studies, including a larger number of patients, with the possibility of dividing into subgroups based on the stage in the two glaucoma disease groups and subgroups with different degrees of therapeutic control of diabetes within the study. This would be much easier if the study were multicenter with a common data recording protocol. Additionally, the study would benefit from analyzing a new parameter represented by ocular perfusion pressure, in order to analyze the vascular mechanism that could be involved in the pathophysiology of the two diseases.

THE USEFULNESS OF GRONINGEN FRAILTY INDICATOR IN THE UROLOGIC PATIENTS AGED OVER 60 YEARS OLD (Abstract): The presence of frailty in an older patient influences his mental status, physical status, his response in stress conditions, including surgery and choosing the proper treatment. The surgical community has recently adopted frailty evaluation as an instrument to estimate the post-surgical risk. Our objective is to evaluate the usefulness of frailty evaluation in the urological patient in terms of post-surgical evolution and post-surgical complications. **Material and methods**: This is a prospective study which included 600 consecutive patients aged 60 and over admitted in Urological Clinic in one year. Demographic data and data regarding comorbidities, urological intervention, hospitalization days and complications were collected. Using Groningen Frailty Index (GFI) patients were divided into two groups: non-frail (GFI 0-4) and frail (GFI 5-15). **Results**: 343 patients with a mean age of 70.24 years were in non-frail group and 257 patients with a mean age of 73.28 years in frail group. Cardiovascular comorbidities predominated in both groups 82.02% (281 patients) in the "non-frail" group and in 84.27% (217 patients) in the "frail" group ($p = 0.4833$). Surgical intervention were performed on 80.39% (276 patients) in the "non-frail" group and on 75.40% (194 patients) in the "frail" group. The rate of post-surgical complications was with 13.7% (34 patients) higher in the frail group ($p = 0.00053$). Frailty is correlated with age ($r = 0.252$, $p<0.0001$), neurological comorbidities ($r = 0.171$, $p<0.0001$) and non-urological malignancies ($r = 0.096$, $p = 0.018$). **Conclusions**: GFI can be a useful tool in the post-surgical evaluation of the elder patients' evolution.
Keywords: FRAILTY, UROLOGICAL OLDER PATIENTS, COMPLICATIONS.

Once with the increase of the average life expectancy, the addressability for conditions that require urological surgery also increases, while an accurate estimation of the surgical risk becomes even more necessary. Elder patients have an increased risk of developing post-surgical complications and major urological interventions (radical nephrectomy, radical cystectomy, prostatectomy etc.) add even more risks. In case these complications occur, they can lead to a multitude of events resulting in a low-quality life, possible loss of independence, high costs of medical care and increased mortality (1). When dealing with an elder patient, taking

the right decision regarding the surgery, becomes difficult and even a real challenge, due to the complexity of elements which play a role in a healthy condition and the lack of instruments which may appreciate/predict the surgical risk (1).

Elements predicting the post-surgical complications commonly used have substantial limitations-most of them are based on a single organ system or are subjective and do not evaluate the physiological supply of the patients (e.g. Lee and Eagle criteria appreciate only the heart function, while the well-known ASA indicator is determined by a subjective estimation of the level of damage in the organ systems and probability of survival) (1, 2). Hence, some elder patients could be subjected to surgical procedures with an unacceptable high risk of post-surgical complications (2, 3). Both the patient and his relatives must be correctly informed about the surgical risk (4, 5) and the possible short-term and long-term complications which may arise, and for now, the urologist cannot offer answers to match the expectations. For the first time in literature, we have tried to evaluate the usefulness of frailty evaluation in the urological patient by using the Groningen frailty indicator in the view of the post-surgical evolution.

The geriatric community acknowledged and developed the concept of "frailty" for a more accurate objectification of the patients' condition, defined as an individual syndrome of physiological supply reduction, which restricts the ability of a patient to respond to stress factors and exposes the patients to adverse reactions/results (1, 6).

The surgical community has recently adopted frailty evaluation as an instrument to estimate the post-surgical risk (2).

The aim of this study is to establish the role that the frailty of the patient-evaluated with the help of the Groningen frailty indicator-can play in appreciating the risks and complications in the pre- and post-surgery periods. It is the first of several studies that explores frailty and its impact on the post-surgical evolution, including oral and maxillofacial surgery, and orthopedic surgery.

The assumed objectives of this study, were: to detect the patients with increased frailty, who could not be identified through other methods (clinical/non-clinical), with the help of the Groningen frailty indicator; establishing the implications of the frailty rate in choosing the urological therapeutic strategy (conservatory/surgical-endoscopic/opened); evaluating the influence of the frailty rate over the surgical risk and subsequent complications.

MATERIAL AND METHODS

In the ongoing study, we have evaluated patients aged over 60 years, hospitalized in the Urology clinic of the "Dr. C. I. Parhon" Hospital in the last 18 months, by filling in a *Groningen Frailty Indicator* (GFI) form at admission. Based on the obtained indicator, these were divided into 2 study groups: 0-4 GFI indicator (considered as "non-frail") and 5-15 GFI indicator (considered as "frail"). The 2 groups were evaluated comparatively in terms of cardiovascular, neurological, pulmonary, metabolic conditions, but also in what the number of hospitalization days and post-surgical complications are concerned.

600 patients aged over 60 years were included in the study. They were hospitalized in the Urology clinic of the "Dr. C.I. Parhon" Hospital between the 1st June 2017 and 1st May 2018. The GFI form was filled in for all the patients, after the informed consent was obtained.

The Groningen Indicator is a tool of screening the level of frailty in patients and includes 15 questions. The questionnaire is divided into 4 geriatric fields: physical function (mobility, daily activities, sight, hearing, weight loss); cognitive function; social function (solitude); psychological function (anxiety, depression).

The categories of answers are positively or negatively formulated variables (0 or 1 point). The indicator may vary from 0 to 15 points. High indicators reveal high levels of frailty: patients with a GFI≥4, were considered as frail. The patients were also asked about the following socio-demographical data: age, gender, civil status, origin environment (urban/rural). The studied age groups were young elders (60-74 years old), adult elders (75-84 years old) and old elders (≥ 85 years old).

Data concerning the following were collected: patient comorbidities (cardiac, neurological, respiratory, metabolic pathologies or other malignancies), urological pathology-malignant, lithiasis. Infectious (urosepsis, orchiepididymitis, prostatitis), others (periurethral adenoma, hydrocele, trauma); surgical intervention (invasive/ opened or minimally invasive/endoscopic); number of hospitalization days; with/ without post-surgical complications.

The statistical analysis was carried out by using *t-Student* and *Chi-Square* and the statistical significance was defined for $p \leq 0.05$.

RESULTS

Between the 1st June 2017 and 1st May 2018, 600 patients hospitalized in the Urology clinic Iasi for a surgical intervention, have filled in the Groningen questionnaire. The patients were aged between 60 and 95 years. Out of these, 33% were women (198 patients) and 67% were men (402 patients). After filling in the questionnaire, 343 patients with a mean age of 70.24 years fell into the Ist study group ("non-frail"), while 257 patients with a mean age of 73.28 years ($p = 0.00001$), fell into the study group of "frail" patients. The origin environment was not significant for the statistics ($p = 0.1034$): in the "non-frail" group, 50.14% (172 patients) were from urban environment and 49.86% (171 patients) from rural environment, while in the "frail" group, 44.35% (114 patients) were from urban environment and 55.65% (143 patients) from rural environment.

Among the associated comorbidities, cardiovascular disease had the highest incidence in both study groups, present in 82.02% (281 patients) of the "non-frail" patients and in 84.27% (217 patients) of the "frail" patients, without being relevant in the statistics between the two categories ($p = 0.4833$).

Neurological conditions (19.35%, $p = 0.000315$), metabolic conditions (33.87%, $p = 0.0196$) and post-surgical complications (13.70%, $p = 0.00053$) had a higher incidence in the "frail" study group, with an impact on the number of hospitalization days, representing an average of 5.97 days (tab. I).

Surgical intervention was carried out on 80.39% (276 patients) of the "non-frail" group and on 75.40% (194 patients) of the "frail" group. In the latter one, the rate of post-surgical complications was with 13.7% (34 patients) higher compared to the "non-frail" group of patients ($p = 0.00053$) (tab. II).

There are no substantial statistical differences regarding the gender of the study group ($p = 0.81$), yet a predominance of male patients can be noticed (tab. III).

TABLE I

Characteristics of the study group according to frailty status

		Non-frail	Frail	p
Number of patients included		343	257	
Age		60-88	60-95	0.000010
Mean age		70.24	73.28	
Gender		F- 95 (26.14%) M-248 (73.86%)	F- 103 (32.66%) M- 154 (67.34%)	0.092954
Environment		U- 172 (50.14%) R-171 (49.86%)	U- 114 (44.35%) R- 143 (55.65%)	0.103400
Comorbidities	Cardiovascular	281 (82.02%)	217 (84.27%)	0.483300
	Neurological	30 (8.82%)	50 (19.35%)	0.000315
	Pulmonary	44 (12.74%)	35 (13.70%)	0.7385
	Metabolic	85 (24.83%)	87 (33.87%)	0.0196
	Other malignancies	25 (7.18%)	32 (12.5%)	0.0345
Urological pathology				0.202

Lithiasis		80	49	
Infectious		41	41	
Others		95	69	
Operated		276 (80.39%)	194 (75.40%)	0.15750
Days of hospitalization		1-64 (5.85)	1-33 (5.97)	0.38400
Complications		16 (5.22%)	34(13.70%)	0.00053

F-female, M-male, U- urban area, R-rural area.

There is a significant statistical difference between the origin environment of the adult elder patients and young elders or old elder ones 116 (60.4%) *vs.* 178 (46.4%) and 12 (50%). Taking comorbidities into consideration, the cardiovascular ones are more frequently encountered in the age group of 75-84 years old (90.1%), compared to the age group of 60-74 years old (79.4%) and the group over 85 years old (83.3%), the difference proving significant in terms of statistics ($p = 0.0006$). The neurological pathology is encountered on a larger scale in the study group of old elders (37.5%) than in the group of young elders (12.2%) and adult elders (14.1%), the difference between these also proving statistically relevant ($p = 0.002$). There are no statistically significant differences in what the pulmonary or neoplasia pathologies are concerned, other than the urological one ($p = 0.299$).

When analyzing the urological pathology according to age groups, statistically significant differences ($p = 0.001$) can be noticed, with a prevalence of the neoplasia pathology, regardless of age, especially in the old elders group (48.5% *vs.* 41.7% and 33.3%). Urological infectious pathology prevails in the age group ≥ 85 years old (25% *vs.* 12.8% and 11.5%), while the lithiasis pathology prevails in young elders (24%) compared to adult elders (17.2%) and old elders (4.2%).

Surgical intervention was carried out with no difference in age in the studied group ($p = 0.219$), encountered in approximately 308 (80.2%) patients aged < 75 years old, in 142 (74%) patients aged be-

tween 75 and 84 years old and in 18 (75%) patients aged over 85 years old. The emergence of complications was similar between the studied groups (35 (9.1%) *vs.* 20 (10.4%) *vs.* 5 (20.8%), p = 0.183).

Elders ≥ 85 years old are frailer compared to the ones from other age groups, so that the GFI has an average of 7 (8-3) in old elders, *vs.* 3 (5-1) in young elders, *vs.* 4 (6-2) in adult elders p<0.0001 (tab. II).

TABLE III

Correlations of frailty with the studied parameters

		r	p
Age		0.252	<0.0001
Gender		-0.067	0.100
Rural		-0.862	0.045
Comorbidities	Cardiovascular	0.006	0.855
	Neurological	0.171	0.000025
	Pulmonary	0.012	0.763
	Malignancies	0.096	0.018
Urological pathology	Neoplasia	-0.002	0.969
	Lithiasis		
	Infectious		
	Others		
Operated		0.055	0.180
Days of hospitalization		0.036	0.379
Complications		-0.173	0.00002

The frailty in the older patients hospitalized for urological conditions, is correlated to age ($r = 0.252$, $p<0.0001$), presence of neurological disease ($r = 0.171$, $p<0.0001$) and non-urological malignancies ($r = 0.096$, $p = 0.018$). Frailty is also correlated to the rural origin environment ($r = 0.862$, $p = 0.045$), GFI proving to be higher in those. The presence of complications was associated to frailty in the elders from the studied group ($p<0.0001$). The days of hospitalization ($p = 0.379$), type of urological pathology ($p = 0.969$), presence of cardiovascular ($p = 855$), pulmonary ($p = 0.763$) conditions and days of hospitalization ($p = 0.379$) were not associated to frailty (tab. III).

DISCUSSION

There are numerous studies searching for the right tools to quantify the actual health condition regardless of age (7). Among these, the Groningen indicator seems to be a useful element in establishing the frailty. Meulendijks *et al.* believe that "frailty" with a reduced level of psychological supply is caused by the accumulation of multiple deficits of the organs, resulting in an extremely low endurance to stress (9). In a study carried out on 1549 patients, Irene Drubbel *et al.* certify the usefulness of the Groningen questionnaire, compared to the Frailty Index (FI).

Currently, approximately half of the surgical interventions from USA are carried on patients older than 65 years old. Based on recent population projections, it is estimated that the average workload of surgeons shall increase from 14% up to 47% between 2000 and 2020, because of the old patients. (1). There is no doubt concerning the fact that these patients require a specific approach and the presence of frailty must be taken into consideration in the treatment scheme (8). Due to similar trends in our population, we perform this study to identify particularities and significance of frailty. In our study group the frailty population as older than the non-frail group with no significant differences between men and women. The prevalence of frailty of 42,83% in our group was higher comparing with other data (21,8% in a study perform by Moro *et al.*) despite the fact that our group included patients over 60 years, compared with 70 years in the other study (29). This may be a characteristic of our population, or an indicator for "the biological age" of our study population considering the high prevalence of comorbidities, over 80 % had concomitant cardiovascular comorbidities, but also metabolic and neurological ones.

Once the patient was identified as frail, the physician can consider the risks and benefits of a potential surgical intervention. In the post-surgery period, it is possible to reduce the risk of complications in the frail ones, through a more careful monitoring, a better hydration, nutrition and mobilization. (1) In a study carried on 594 patients aged ≥65 years old, who needed an elective surgical intervention, Martin A. *et al* shows that frailty is an independent factor which predicts post-surgical complications and the number of hospitalization days. (1) These data comply with the results of our study, where frail elders had greater complications compared to the non-frail since the frailty indicator is associated with the emergence of complications. This can be the context for body homeostasis condition, affecting the adaptive ability and association of sarcopenia. All the things mentioned above are body modifications in the context of the emergence of a frail state

and negatively influence the response of the body to stress, causing an increased risk of morbi-mortality (14, 15). Post-surgery complications are frequent in frail-group, but also depends of patients age. In our study, the very old group, aged over 85 years, 20.8% had complications, compared with those below 75 years of age; and the older the patient, the higher the GFI. Similar findings were described in a previous study which included 95,108 urologic cases representing 21 urologic procedures. They found that frailty is strongly associated with both major and minor complications among patients undergoing urologic surgery. Moreover, frailty had a significant association with complications for most urologic procedures examined. (30) Louis M Revenig et. al carries out a similar study on 80 patients and finds the same negative impact on the post-surgical evolution in patients categorized as "frail" after filling in the questionnaire, compared to those considered as "non-frail" and even reported an increased incidence of post-surgical complications in case of open, extensive, elaborate surgical interventions, compared to the endoscopic, urological and minimally invasive ones (6). Further data emphasis the fact that the presence of frailty is a strong predictor of high-grade post-operative complications and mortality following radical cystectomy in bladder cancer patients. Thus, frailty has the potential to be a very clinical aspect for risk stratification and perioperative counseling of bladder cancer patients (31).

Frailty and the emergence of post-surgical complications bring about the increase of the hospitalization period and mortality (16, 17, 18). In our study group, the hospitalization period was similar in frail and non-frail patients and also with no differences regarding patients age (considering the three groups). The explanation results from the multi-disciplinary collaboration in the hospital, which facilitated the post-surgical identification of frail elder patients. Hence, corrective actions could be carried out and a customized tracking of these could be established, while post-surgery, patients were transferred in the Geriatric Clinic, if the case.

The geriatrist R. E. Hubbard and anesthesiologist D. A. Story defined frailty and its quantification as "an elephant in the operating room: easy to spot, yet often ignored". They define frailty as that increased vulnerability of the geriatric patient to intra and post-surgical stress, seen as the mirror of the normal process of aging, but which manifests differently; although there are validated algorithms and questionnaires, it is difficult to quantify the elements leading to an increased risk up to being unacceptable, when talking about an elder patient going into the operating room (12, 32).

Only one study, carried out in Romania by Marinela Olaroiu (13) validates the Groningen indicator as useful in evaluating elder patients' frailty and finds a much greater prevalence in Romanian patients compared to the Dutch ones. Thus, this study provides significant data regarding frailty in elders hospitalized for urological conditions. The great number of patients included in the study increase the importance of the results, since they can be extrapolated to other similar populations. Also, this study is one of the few studies which stress out the necessity of post-surgical evaluation of frailty in the urological patient, even in the surgical one, and of collaborating with the geriatric team in order to reduce the complications and hos-

pitalization period.

There are several limitations to our study including a limited follow-up period, leading to an underestimation of complications. The anesthesia type is not recorded, and the literature data described a relationship between depth of anesthesia and impaired postoperative also suggested a more pronounced impact on the elderly and especially in pre-frail or frail patients (33). Also, data about the cognitive status, sarcopenia and other geriatric syndromes is lacking (34, 35). These data emphases the need for further studies.

CONCLUSIONS

In order to make a correct decision regarding the surgical treatment, it is useful to establish whether the patient is frail or not, by taking into consideration the tight connection between frailty and the increased risk of developing post-surgical complications.

A large part of the urological patients is over 60 years old and anticipating the emergence of post-surgical complications within the context of their age, surgical intervention and comorbidities, is still a challenge. The experience accumulated from those 600 patients indicates the fact that the Groningen indicator can be a useful tool in the post-surgical evaluation of the elder patients' evolution.

EVALUATION OF THE EFFECTS OF BIOCOMPATIBLE MATERIALS ON CELL DEVELOPMENT ON PULP STEM CELLS IN DIRECT PULP CAPPING

A group of researchers have studied the effects of widely used biomaterials in direct capping, using the in vitro method on pulp stem cells. The osteogenetic, odontogenetic and angiogenetic effects of ProRoot MTA (Dentsply Tulsa Dental Specialties, Johnson City, TN, USA), Dycal (DENTSPLY Caulk, USA), Biodentine (Septodont, USA) or Emdogain Gel 30 mg/ml (BIORA AB/Straumann, Switzerland) were studied on stem cell cultures. The analyzes of the genetic markers were performed during a time span of 7 to 14 days following the beginning of the experiment and the goal was to preserve the pulp vitality in the cases group compared to the control group. Statistical analysis was done by one-way ANOVA. The study revealed that Emdogain has a lower cytotoxicity than the other materials. In the case of osteogenesis and odontogenesis it was concluded that all 4 materials stimulate these processes, but Dycal exhibited lower results in angiogenesis, compared to the other materials. Therefore, Emdogain can be a successful material in direct capping due to its biological properties, particularly involved in pulp regeneration (Abdel-Rahman Y., Ramy E., Mohiuddin M. T., Faisal A. Al-Alla, Majed A., Mazen A. A, Shahid S. S. Effects of mineral trioxide aggregate, calcium hydroxide, biodentine and Emdogain on osteogenesis, Odontogenesis, angiogenesis and cell viability of dental pulp stem cells. *BMC Oral Health* 2019; 19: 133).

HYDATID CYST WITH MULTIPLE LOCALIZATION. CASE REPORT

HYDATID CYST WITH MULTIPLE LOCALIZATION. CASE REPORT (Abstract): We present the case of a 21-year-old male, admitted in our Clinic with pain in the left upper quadrant, without any other complains. The biochemical tests were normal, except the Ig E for the hydatid cyst was 668 U/mL with the reference value of 0-87 U/mL. The ultrasound and the computer tomography revealed the presence of cystic tumors in the liver, right lung and in the spleen, with imagistic appearance specific for hydatid cyst. A multidisciplinary surgery team was formed from General Surgery and Thoracic Surgery to perform, in one surgical session, the resection of the multiple cysts, first time through thoracotomy followed by laparotomy. The histopathological examination confirmed the diagnosis of multiple hydatid cyst. **Keywords:** HYDATID HEPATIC CYST, *ECHINOCOCCUS GRANULOSUS*, PERICYSTECTOMY, OPEN SURGICAL APPROACH.

The human hydatidosis is a potentially serious, sometimes fatal, condition caused by cysts containing the larval stages of the *Echinococcus granulosus* (*E. granulosus)* tapeworm that infect dogs and other canines . The tapeworm eggs are excreted in feces of these infected animals and people become infected by ingesting them. The contamination can occur via hand-to-mouth transfer after handling dogs or objects contaminated with the eggs, or from consuming contaminated food or water (1). The uncomplicated hydatid cyst, in most of the cases, is asymptomatic. The diagnostic is established by random abdominal echography or during the surgery performed for another pathology. There are cases were the hydatid cyst was first diagnosed in surgical intervention performed for another pathology, or even during necropsy. The hydatid cyst can be asymptomatic for many years, the clinical manifestations appears in case of large dimensions, depending of the location of the cyst and his complications.

CASE REPORT

We present the case of a 21-year-old male, admitted in our clinic with pain in the left upper quadrant, without any other complains. The biochemical tests were normal, except the Ig E for the hydatid cyst was 668 U/mL with the reference value of 0-87 U/mL. The ultrasound and the computed tomography revealed the presence of

cystic low-density mass in the right lobe of the liver, without signs of calcification of the pericyst of 94/70/88 mm, 207cm^3 in the segment V-VI of the liver, 112/90/99 mm, 560 cm^3 in the spleen (fig. 1), and 60/40 mm in the right lung (fig. 2), with imagistic appearance specific for hydatid cyst.

The patient was on Albendazole 800 mg/day for 22 days with a pause from the treatment for 14 days before the surgical procedure.

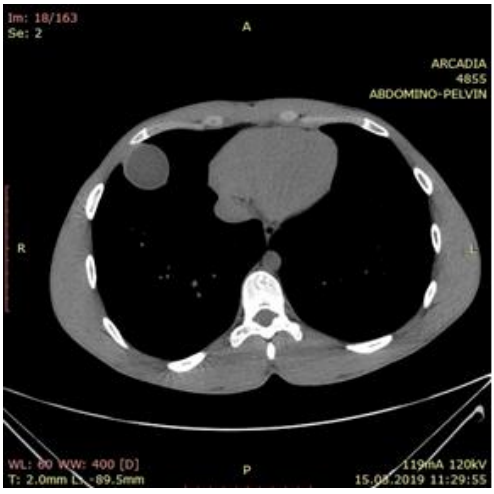

Fig. 1. Cystic tumor in the lung**.**

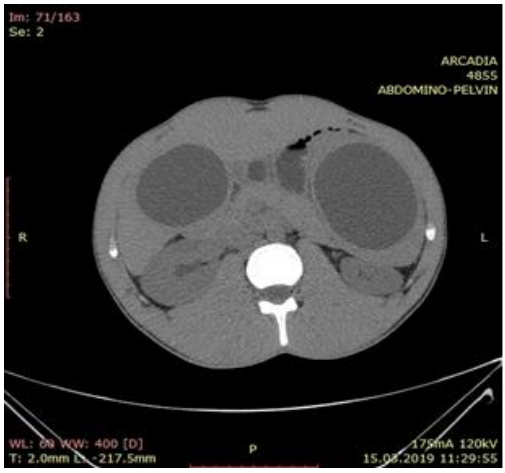

Fig. 2. Cystic tumor in the spleen and liver.

A multidisciplinary surgery team was formed from General Surgery and Thoracic Surgery to perform in one surgical session the resection of the multiple cysts, first time by thoracotomy (fig. 3) followed by laparotomy (fig. 4), with the total cystectomy (fig. 5).

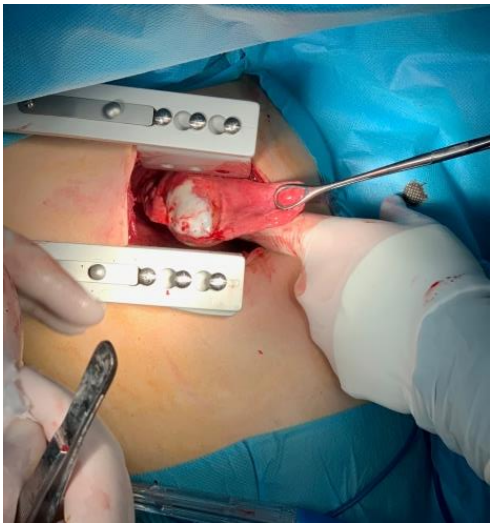

Fig. 3. Removal by thoracotomy

Fig. 4. Removal by laparotomy

Fig. 5. The total cystectomy

The anesthesiologist did the induction in the supine position. A selective bronchial intubation was applied, the endotracheal tube was advanced into the left main bronchus. After that the patient was positioned in the lateral decubitus with the operated side up. He is immobilized with sandbags or a beanbag that is used to support the back and abdomen. Strips of adhesive tape and/or a belt are passed over the hips and secured to the table. The lower arm is on an arm board at a right angle with the table, while the upper arm is rotated forward and upward, and fixed at the elbow. The legs are separated with a pillow. The lower leg is flexed at the knee, while the upper leg lies straight on top of the pillow. To increase the spread of the intercostal space and, thus, facilitate entry into the pleural space, the table can be angulated, or a roll can be inserted under the patient's chest. During positioning, it is important to support the arm and shoulder to prevent brachial plexus or shoulder injuries. These injuries are not uncommon, and they can be the source of pain or immobility of the shoulder postoperatively.

The thoracic team did a postero-lateral thoracotomy, with the reveling of the hydatid cyst in the inferior right lobe and performed a total cystectomy (fig. 3). The pulmonary tissue was sealed with a linear white stapler. A pleural drainage was put in the pleural cavity and the thoracic wall was closed in anatomical plans.

After the thoracic procedure we turn the patient in a supine position and a median laparotomy was performed. We performed a splenectomy and total hepatic cystectomy without incidents. A peritoneal irrigation with hypertonic saline was not necessary because of the removal of the intact cysts (fig. 5). No biliary fistula were revealed. We did the drainage of the splenic lodge, hepatic resection site and Douglas space.

After the surgery the patient evolution was favorable, and the drainage tube were removed consecutively after thoracic x-ray and ultrasound was performed.

DISCUSSION

The liver is the most common location of the hydatid cyst, followed by the lung, with the approximate occurrence rates of 70% and 12%, respectively. In the general population the occurrence of synchronous multiple localization is about 4-25%, in a smaller rate in the spleen. The classic surgical attitude in multiple localization is to perform the thoracic cystectomy and after a time the abdominal intervention to remove the cysts.

The hydatid disease has many complications, such as rupture, suppuration or calcification, but the most common problem is the surgical one represented by the multiplicity of cysts. The approach is difficult in the up mentioned situation requiring sound

operative experience, preferably with a one-stage procedure following appropriate preoperative preparations (2, 3, 4). We performed in one surgical session the resection of the multiple cysts, first time by thoracotomy followed by laparotomy, because the patient was young, in perfect health.

As of now, the surgical management is still the treatment of choice for most cases of hydatid hepatic cysts. It remains the single method that provides complete eradication of the parasite, treatment or prevention of complications and evasion of relapse.

In the table below are presented the indications for surgical management (tab. I) (5).

TABLE I

Indications for surgical treatment of hydatid echinococcal hepatic cysts.

Indications	Contraindications
• Superficial cysts with a high rupture risk • Large cysts, containing multiple daughter cysts • Hepatobiliary communication • Compression of neighboring organs (symptomatic) • Pus containing, infected echinococcal cyst • Nonhepatic echinococcal cysts (lungs, kidneys) • Cysts exerting pressure on adjacent vital organs	• Multiple cysts • Inactive, difficult to access cysts • Dead cysts • Inactive cysts that are partially or totally calcified • Very small cysts • unsuitable patient's condition

To decide the treatment in case of multiple hydatid cyst it is very important to know the physical condition of the patient and the characteristics of the cysts.

When the surgical treatment is not indicated the options are drug therapy along with systematic monitoring of the patient with or without the nonsurgical techniques (*wait & watch approach*).

The desired results of the surgical treatment are the entire removal of the cyst, the prevention of intraoperative contamination of the intraperitoneal cavity, the treatment of the remaining hepatic parenchyma and the identification and treatment of possible hepatobiliary communication.

Generally, the surgical treatment is reserved for complicated cysts, such as the ones that develop a biliary fistula, the perforated cysts or the ones that have daughter cysts inside. If the cysts are superficial ones, smaller than 10 cm, and the patients are not suitable for the percutaneous treatment then the surgical treatment is the election one.

There are three treatments options: a conservative open approach, a radical open approach and a laparoscopic approach (6). Before surgery, no matter the chosen approach for each and every patient, the medical treatment with benzimidazole must take place in order to obtain sterilization of the cyst content and to prevent dissemination and anaphylactic shock.

In all cases, the precautions taken to eradicate even the protoscolioces of the parasite within the content of the cyst, has to be drastic. Isolating the operating field has to be done scrupulously and also using solutions capable to eliminate all cells of the parasite (7).

CONCLUSIONS

The hydatid disease is still a major

problem in the public health system and the main goal, no matter the treatment chosen, has to be parasite elimination along with no recurrence and with minimal morbidity and mortality. Even though the surgical procedures are the best therapeutic option the right technique has to be chosen considering the uniqueness of each patient.

MERIDIAN DIAGNOSTIC ACCURACY STUDY: CLINICAL AND FINANCIAL BENEFITS OF iuMRI

Fetal brains anomalies are found in 1% of pregnancy and 10% of perinatal autopsies, posing a huge burden to the healthcare system. The main technique of screening and diagnosis at the moment is represented by ultrasonography, but this method is associated with an important number of cases of incorrect diagnoses and inaccurate counselling. A group of researchers from the UK performed a prospective multicenter cohort study together with a health economics analysis in order to assess the diagnostic impact, acceptability and cost consequence of intrauterine Magnetic Resonance Imaging (iuMRI) among fetuses with a suspected fetal brain abnormality. After evaluating 570 pregnancies, they reported that iuMRI significantly improves the diagnostic accuracy and confidence for the detection of fetal brain abnormalities, with a small increase in early examination costs but a decrease in cost per management decision. In conclusion, iuMRI can be an excellent diagnostic tool for fetal brain anomalies with a good cost efficiency for the healthcare system. (Griffiths PD, Bradburn M, Campbell MJ, Cooper CL, Embleton N, Graham R, *et al*. MRI in the diagnosis of fetal developmental brain abnormalities: the MERIDIAN diagnostic accuracy study. *Health Technol Assess.* 2019; 23(49): 1-144).

RETROSPECTIVE STUDY OF DECOMPRESSIVE CRANIECTOMY IN THE TREATMENT OF MALIGNANT BRAIN EDEMA

RETROSPECTIVE STUDY OF DECOMPRESSIVE CRANIECTOMY IN THE TREATMENT OF MALIGNANT BRAIN EDEMA (Abstract): The aim of this paper is to study the evolution of patients with MCA stroke who developed MBE during hospitalization and underwent decompressive craniectomy after a failed conservative treatment. **Material and methods:** This is a retrospective a single-center study of 20 patients with malignant brain edema following an ischemic stroke who were surgically managed with decompressive craniectomy at Sibiu County Emergency Hospital between January 1st, 2015 and April 30th, 2019. **Results:** The sample was comprised of 7 women (35%) and 13 men (65%). 7 patients (35%) were under 60 years old and 13 (65%) were over 60 years old. We observed the three highest-ranking risk factors are: high blood pressure (20 patients - 100%), males and elderly both represented an equal risk category (13 patients-65%) and smoking (12 patients-60%). No patient had any surgery-related complications: 4 patients (20%) had bronchopneumonia, 1 patient (5%) had pneumonia, 1 patient (5%) had a urinary tract infection and 11 patients (55%) had irreversible cardiorespiratory arrest. At discharge, 9 patients (45%) had an ameliorated state and 11 patients (55%)died. **Conclusions:** Decompressive craniectomy is not a panacea and it is well known that patients will not return to the state before the pathology. It is unanimously accepted that patients who undergo surgery have a higher chance of life even if, in some patients, the quality of life is low. **Keywords:** ISCHEMIC STROKE, MALIGNANT BRAIN EDEMA, CRANIECTOMY, NEURO-SURGERY.

Malignant brain edema (MBE) occurs only in certain patients who have suffered ischemic stroke of the middle cerebral artery (MCA) and is characterized by neurological damage due to progressive edema, increased intracranial pressure and cerebral hernias. Only a certain subgroup of patients develops MBE. Although there are certain factors that can predict the development of edema, it is currently impossible to identify patients who will develop MBE. This leads to a worsening of the patient's health and poses a risk of

death. (1)

According to the World Health Organization (WHO), stroke affects 6.2 million lives annually and high blood pressure (HBP) is the main risk factor. In the U.S., stroke is the fifth leading cause of death, with approximately 795,000 deaths per year. (2)

By increasing life expectancy, it is estimated that in 2025, 1.5 million Europeans will suffer one stroke per year. Recently, it has been shown that the incidence of ischemic stroke is increasing among the young population in Europe (3). Several explanations for this trend have been proposed, including increasing the prevalence of diabetes, hypercholesterolemia, obesity, smoking, alcohol abuse, and illegal drug use among the young population (4).

Although there are many scales for the emergency patient (Canadian Neurological Scale, European Stroke Scale, NIHSS, Scandinavian Stroke Scale, etc.) there is no patient evaluation scale that could indicate the evolution to MBE of the MCA, the most common cause of death in ischemic stroke patients.

MATERIAL AND METHODS

Patient population

We performed a retrospective single-center study of 20 patients diagnosed with MBE who were surgically managed with craniectomies and subsequent cranioplasties at Sibiu County Emergency Hospital between January 1st, 2015 and April 30th, 2019.

Of all 3,591 patients admitted with ischemic stroke, 2,989 were in the territory of the Middle Cerebral Artery (MCA) with either a thrombotic or embolic origin. During their hospitalization at the Neurology Department, 20 patients with MCA stroke complicated with MBE confirmed by imaging explorations (CT-scan, Angio-CT and Angio-MRI). Those patients could not be treated conservatively and were transferred to the Neurosurgical Department for decompressive craniectomies.

Our exclusion criteria are:

- ischemic stroke in other territories vascular territories,
- Glasgow Coma Scale (GCS) lower than 3 points,
- refusal of surgical treatment by the patient's family

Data collection

A retrospective chart review was conducted. Demographic data (sex, age, origin community), risk factors (high blood pressure (HBP), dyslipidemia, diabetes mellitus, arterial fibrillation, toxic substance consumption), clinical data and diagnosis, paraclinical diagnosis (bio-humoral surveys, CT-scans), evolution and complications were collected.

RESULTS

The sample was comprised of 7 women (35%) and 13 men (65%). 7 patients (35%) were under 60 years old and 13 (65%) were over 60 years old. 12 patients (60%) were from an urban household and 8 patients (40%) from a rural household.

Analyzing the distribution of age in relation to origin community (tab. I) we observe that elderly patients (> 60 years old) have an urban origin. Patients under 60 years old have an equal distribution regarding origin community.

TABLE I.

Origin community in relationship to age

Urban		**Rural**	
<60 years	>60 years	<60 years	> 60 years
5 (25%)	7 (35%)	4 (20%)	4 (20%)

We divided risk factors in two categories: changeable and unchangeable (tab. II, III).

We observed the three highest-ranking risk factors are: HBP (20 patients - 100%), males and elderly both represented an equal risk category (13 patients - 65%) and smoking (12 patients - 60%).

TABLE II.
Changeable risk factors

	Frequency	Percentage
High Blood Pressure	20	100%
Atrial Fibrillation	7	35%
Other cardiac diseases	18	90%
Dyslipidemia	11	55%
Smoking	12	60%
Obesity	7	35%
Diabetes mellitus	11	55%
Alcoholism	5	25%

TABLE III.
Unchangeable risk factors

	Frequency	Percentage
Age		
< 60 years old	7	35%
> 60 years old	13	65%
Gender		
Male	13	65%
Female	7	35%
Previous vascular episodes		
Ischemic Stroke	5	25%
Transitory Ischemic Stroke	2	10%
Peripheral Vascular Disease	12	60%

The topographic localization of the ischemic stroke was established following a CT-scan. The distribution is equal: 10 patients with ischemic stroke on left MCA and the other half with stroke on the right MCA.

State of consciousness at admission in the Neurosurgical Department was assessed using the GCS. 10 patients (50%) were unconscious (GCS < 8), 8 patients (40%) were obtunded (GCS 9-12) and 2 patients (10%) were conscious (GCS > 12).

The average patient hospitalized in the Neurological Department worsened in a period of 12 to 48 hrs. In the first 12 hrs., 6 patients (30%) had deteriorated their state of consciousness, by developing MBE (confirmed by CT-scan) and was transferred to the Neurosurgical Department for surgical management. At 24 hrs., 5 patients

(25%) were transferred for surgery and predominately at 48h the rest of the patients (9 cases - 45%) were transferred.

No patient had any surgery-related complications. All complications are related to the patient's associated diseases, length of hospitalization and rapid cerebral edema uncontrollable even after decompression. Thus, 4 patients (20%) had bronchopneumonia, 1 patient (5%) had pneumonia, 1 patient (5%) had a urinary tract infection and 11 patients (55%) had irreversible cardiorespiratory arrest.

At discharge, 9 patients (45%) had an ameliorated state and 11 patients (55%) died. Death occurred preponderant in elderly patients (63.63%), respectively male (36.36%) (fig. 1).

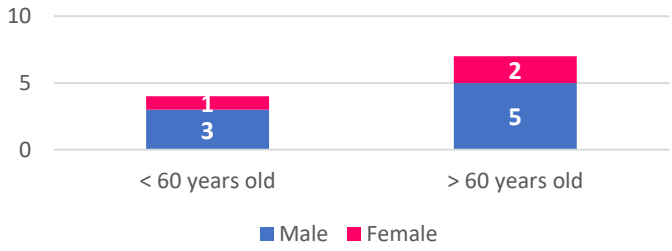

Fig. 1. Representation of deceased patients based on sex and age

DISCUSSION

According to literature, women have a higher chance of having a stroke in their lifetime but also a higher rate of post-stroke death, a higher rate of disability, dementia and depression compared to men. This is attributed to their longer life expectancy, which suggests that age is the strongest non-modifiable risk factor and is a negative predictor of outcome (5, 6).

Of the total number of patients who were transferred to the Neurosurgery Department developing MBE, mainly 60% come from urban areas, which may call into question the greater extent of risk factors in them (disorganized diet, unhealthy lifestyle , daily stress).

Ischemic stroke is a heterogeneous, multifactorial pathology influenced by modifiable and non-modifiable risk factors. In addition to the etiology of ischemic stroke, the risk factors for the underlying disease must be identified and treated at the same time. In our study all patients had at least one type of changeable risk factor. This suggests that lifestyle changes can have an impact in preventing MBEs.

Chronic consumption of toxins determines the acceleration of atheromatosis of the cerebral vessels. Tobacco is a risk factor by acting on the vascular caliber causing vasoconstriction. It affects the heart rate, causing tachycardia. Smoking also affects the lipid metabolism and increases the number of circulating catecholamines. The risk is present in both active smokers and former smokers for about 3 years after abstinence (7).

Some studies have shown the protective effect of moderate alcohol consumption, but chronic alcohol consumption is associated with the risk of hemorrhagic stroke. Chronic toxic substances consumption has the effect of inducing endotheliosis and hyalinization of the capillary wall (8).

Cardiovascular insufficiency, ischemic

heart disease, heart rhythm and conduction disorders, dysmetabolic diseases, ischemic brain events in the past are target points for the patient with stroke and MBE.

HBP is involved in the etiology of stroke by changing the quality of vascular walls. In our study, all patients were known to have HBP at the time of admission. Also, 7 patients had a personal history of atrial fibrillation, a pathology known for the major risk in stroke that increases with age. Cohort studies have shown that arterial fibrillation is a major contributing factor to stroke and a strong predictor of mortality after the first episode of stroke. Another fact observed is that this rhythm disorder is more common in older women (9, 10).

Decompressive craniectomy in MBE is a controversial topic because this life-saving maneuver is burdened by multiple complications and an increased mortality rate. However, studies have shown a lower mortality rate of patients undergoing this surgical maneuver compared to those treated only conservatively. Another important aspect is the reintegration of the patient with disability into society depending on its degree. There are studies that do not recommend decompressive craniectomy in patients older than 60 years due to adverse outcomes, but we should also consider the studies that have shown a survival rate between 6 months and one year in patients over 60 years (11, 12, 13).

CONCLUSIONS

Massive and non-responsive cerebral edema was the main post-operative complication (during hospitalization in the intensive care unit), which eventually led to irreversible cardiorespiratory arrest and death (11 cases).

The precocity with which the stroke patient is transferred to the Neurosurgery Department after a positive diagnosis of MBE is the key to saving them. Emergency imaging examination remains computed tomography, shortening the patient's path to life-saving intervention - decompressive craniectomy.

The aim of a fast, "ultra-early" operative intervention is to reduce the mortality rate, not the disabilities that are permanent consequences of stroke.

Decompressive craniectomy remains the only chance of survival for patients who develop MBE after an episode of stroke, most commonly of MCA.

LIMITED INTERNAL COMBINED WITH EXTERNAL FIXATION OR SIMPLE EXTERNAL FIXATION IN TREATMENT OF OPEN TIBIAL DIAPHYSEAL FRACTURES ?

The conclusion of a recent article published in BMC Musculoskeletal Disorders is that the limited internal fixation combined with external fixation had good results compared with simple external fixation for managing open fractures. The researchers evaluated that additional internal implants did not significantly increase the risk of infection. In contrast, the combined fixation technique was beneficial for initial reduction and subsequent fixation stability, thereby permitting early rehabilitation and rapid healing with a low incidence of postoperative complications. More prospective comparative studies with larger samples and longer follow- up periods are required to accurately evaluate the clinical outcomes of this combined technique (Hao ZC, Xia Y, Xia DM, Zhang YT, Xu SG. Treatment of open tibial diaphyseal fractures by external fixation combined with limited internal fixation versus simple external fixation: a retrospective cohort study. *BMC Musculoskelet Disord* 2019; 20(1): 311. STATURE-WEIGHT RETARDATION AND PROTEIN-ENERGY MALNUTRITION IN CHILDREN WITH CHRONIC DIALYSIS (Abstract): Growth retardation is an important problem in children with chronic renal disease, and malnutrition is a determinative factor. **Aim**: The study intends to assess the relationship between protein-energy malnutrition and stature-weight retardation in children enrolled in chronic dialysis program. **Material and method**: The study group was composed of 16 children (5 boys and 11 girls - sex ratio of 2.2) hospitalized in the IVth Nephrology Clinic at Clinical Emergency Hospital "St. Maria" Iaşi, 13 rural and 3 urban, aged between 9 and 17 years, with chronic dialysis program. This was a follow-up study during a period of 4 years (2006-2009), resulting in correlations between anthropometric paremeters, biochemical, BIA and DEXA data. **Results**: The stature-weight deficiency of the 16 patients was as follows: after an average period of 61.7 months of HD and 32.7 months of PD, in children older than 12 years (mean age 15.27 years), 7 of 10 had stature-weight deficits higher than (-3DS) or (-4DS). The group with less than (-2DS) stature-weight deficits showed the same mean age of 15.2 years, the protein energy-malnutrition was present in 2 cases (33%) and was attributed to a dialysis period shorter than 13.8 months. **Conclusions**: The late diagnosis of the disease (at an average age of 13 years), the long period of chronic dialysis program (over 39.5 months on average) and the early debut of malnutrition are favoring or worsening factors of stature-weight retardation. After correlating ESG with biochemical, BIA and DEXA data, in our group were identified 4 cases of moderate malnutrition and 9 cases of severe malnutrition. **Key words**: MALNUTRITION, DIALYSIS, CRF, DEXA

GIANT MALIGN OCULAR MELANOMA TREATED BY SELECTIVE ARTERIAL EMBOLIZATION AND EXENTERATION. CASE REPORT

GIANT MALIGN OCULAR MELANOMA TREATED BY SELECTIVE ARTERIAL EMBOLIZATION AND EXENTERATION. CASE REPORT (Abstract): Although rare**,** uveal melanoma is the most frequent primary malign tumor of the eye in adult population. If discovered in early phase, several conservative therapies are available, which can help the patient to preserve the eye and even the visual function: brachytherapy, proton beam radiotherapy, stereotactic radiotherapy, laser ablation or endo photocoagulation and limited resection of the tumor. In up to 40% of cases, enucleation is required due to tumoral increased size, while exenteration is required only exceptionally, in loco-regional advanced tumors. The paper presents the case of a patient diagnosed with ocular melanoma 12 years ago but refused surgery. She returns with a giant tumoral mass, complete disorganization of the eyeball and extensive extraocular lateral invasion, but no metastatic disease. Selective arterial embolization under angiographic control followed by exenteration were performed, with no local or at distance recurrence in a 2-year follow-up period. The disease course was favorable, despite many risk factors for poor prognosis. The patient is still checked regularly for metastatic disease, which remain a high risk for the following 10-15 years. **Conclusions**: Angiographic embolization may reduce the intraoperative risk of hematogenous dissemination and improve survival in regionally advanced ocular melanomas. The case was challenging due to increased size of the tumor, yet the predominantly lateral extension, spearing the orbital bones and intraconal space were positive factors for favorable outcome. **Keywords:** CILIARY BODY MELANOMA, SELECTIVE ARTERIAL EMBOLIZATION, EXENTERATION.

Although rare**,** uveal melanoma is the most frequent primary malign tumor of the eye in adult population. It is more common in individuals with fair skin and light-colored eyes and has an incidence of approximately 6 per million per year in white race. Other general factors are considered exposure to UV rays and inherited conditions like ocular melanocytotic, dysplastic nevus syndrome(1, 2). Most of them (90%) origin from the choroid, the remaining may arise from melanocytes of the iris and ciliary body (3). The main modalities of tumor dissemination are: transscleral extension, extension via optic nerve of by hematogenous dissemination, most frequently to liver. It is estimated that 40% of patients with ocular melanoma will develop hepatic metastasis in 10 years, with a poor prognostic of survival (4).

If discovered in early phase, several conservative therapies are available, which can help the patient to preserve the eye and even the visual function: brachytherapy,

proton beam radiotherapy, stereotactic radiotherapy, laser ablation or endo photocoagulation and limited resection of the tumor(3, 5-7). In up to 40% of cases, enucleation is required. Determining factors for this operation include large tumor size, extensive involvement of the ciliary body or iris, and proximity to the optic disc. Exenteration is required only exceptionally, in loco-regional advanced tumors (7).

CASE REPORT

The paper presents the case of a female patient, from an urban area, aged 47, who presents to the ophthalmologist for a progressive decrease in vision in her right eye (RE). At the ophthalmological examination, a visual acuity of light perception is found in the right eye and a normal vision of 6/6 in the left eye. Applanation tonometry revealed normal intraocular pressure of 14 mmHg in both eyes.

Fundus and ultrasound exam highlighted large tumoral mass, which fills 2/3 of the posterior pole, originating in the supero-temporal ciliary body, with surface hemorrhages, cloudy vitreous and partial retinal detachment, in the lower sector. The probable diagnosis was malignant melanoma of the ciliary body in the right eye.

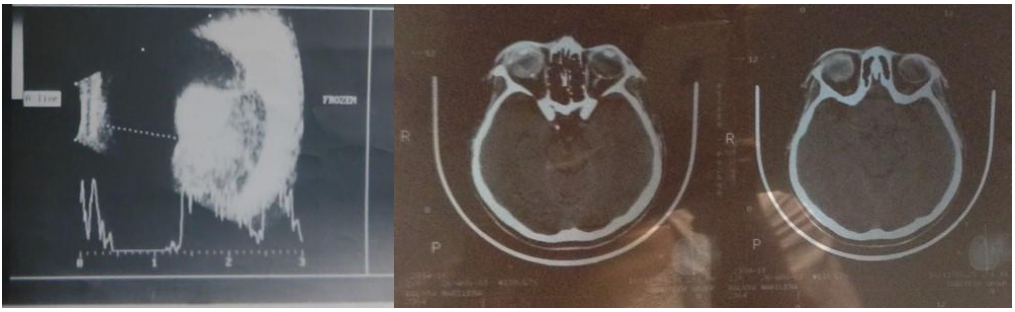

Fig. 1. a) Right eye: Ultrasound exam reveals the hyperechogenic tumoral mass in the posterior segment of the eye; b) CT aspect: increased hyperdense mass in the right eye, adjacent to the lens

The native and contrast-enhanced CT examination reveals a hyperdense formation with an irregular contour, with calcification ranges at the level of the ocular posterior pole, which makes a common body with the lens, but which does not infiltrate the adjacent sclera (fig. 1). Ultrasound and radiological screening of liver and lung metastases is negative.

The patient is recommended enucleation, for the cure with oncological visa of the eye tumor, but she refuses on her own responsibility, declaring that she wants to follow only natural treatments and has not returned to regular control.

12 years later, the patient returns to the clinic for gigantic oculo-orbital tumor, with areas of necrosis, spontaneous bleeding, the eyeball being completely disorganized and superior eyelid of purplish color and dilated tortuous veins (fig. 2).

The CT examination reveals this time a voluminous expansive process located at the level of the right orbit, developed mainly in the extra orbital area, with heterogeneous necrotic tissue structure and areas of hematic density, measuring overall 43/47 mm in axial plane and 52 mm cranio-caudal, with polycyclic contours without demarcation limit to the right

lacrimal gland and encompassing the anterior slope of the eyeball without extension to the intraconal space; disorganized eyeball with multiple microcalcifications, without bone, endosinusal or endocranial involvement (fig. 3).

Fig. 2. Giant tumor with complete disorganization of the right eye: areas of necrosis and spontaneous bleeding

Liver ultrasound and pulmonary radiological evaluation do not show the presence of metastases, despite its long evolution and very large size.

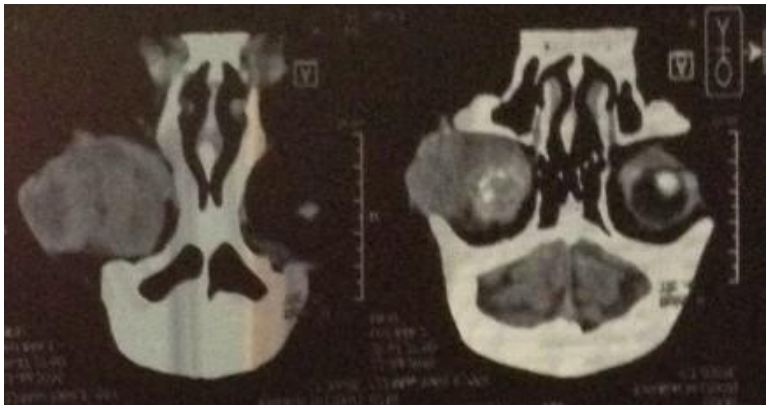

Fig. 3. CT aspect after 12 years, with important increased in size of the tumor, and antero-lateral extension to the adjacent soft tissue

The patient decides that she agrees with the hospitalization for surgical treatment. Cerebral angiography is performed by transfemoral approach that highlights pathologically marked loading on the projection area of the right eye and periorbital globe from multiple terminal branches of the right ophthalmic artery and right maxillary artery. Selective embolization of the terminal branches of the right maxillary artery with 700-micron particles is practiced, with optimal postembolization result and lack of load at the level of the tumor (fig. 4).

Fig. 4. 24 hours post-operatory aspect, with mild eyelid edema and serous-sanguinolent secretion

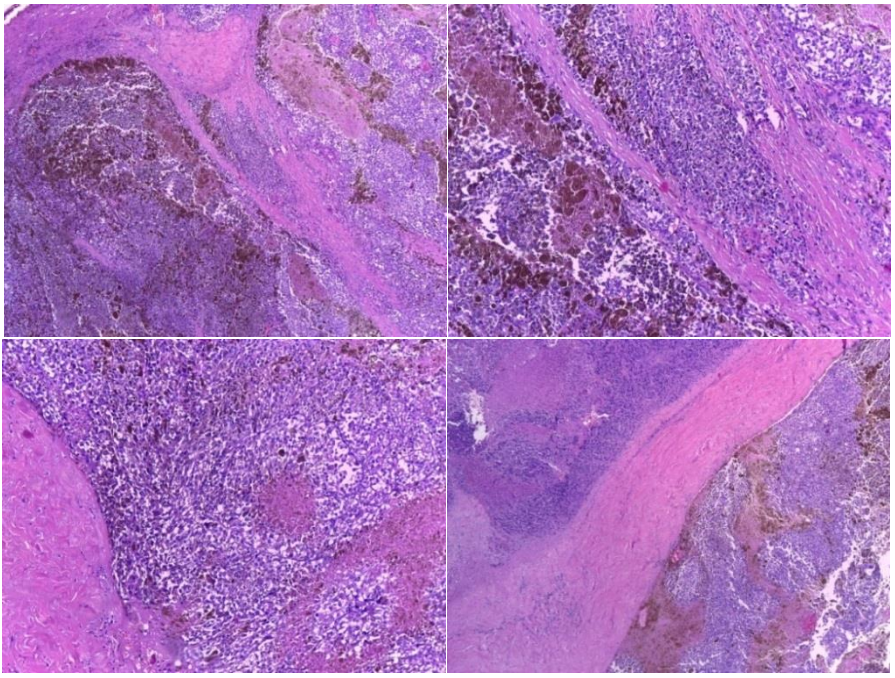

Fig. 5. Giant orbital melanoma: histopathological aspects: a) HE staining (10X10) areas of melanic cells, oval, with hyperchromic nuclei, pleomorphic, with atypical mitoses, conjunctival invasion area (dissected collagen bundles); brown-brown melanin pigment; b) HE staining (10X20) atypical melanoma cell ranges - conjunctival invasion area, foci of tumor necrosis and melanic pigment areas intracellular and extracellular; c) HE staining (10X20) diffuse area of melanic cells with atypical, pleomorphic, vesicular nuclei, pale or clear cytoplasm, melanic pigment and 2 areas of necrosis; peripheral fragment of sclera (low cellular density, eosinophilic area); d) HE staining (10X10) sclera fragment-eosinophilic thick band and areas of malignant melanoma with foci of necrosis on either side of the sclera.

Subsequently, the exenteration of the right orbit is practiced, under general anesthesia, in the mixed ophthalmic-neurosurgical team, with a favorable postoperatory evolution. The excised piece was sent for anatomopathological examination, which highlights giant orbital malignant melanoma, with marked peri scleral extension, epithelioid type, with areas of necrosis and bone metaplasia (fig. 5).

Postoperatively, the patient was examined at one week, one month, 3 months and after that bi-annually, being in a good condition, with the absence of local tumor recurrence or hepatic metastatic dissemination in 2 years follow-up.

DISCUSSION

The particularity of the case was the decision of the patient not to follow the ophthalmologist recommendations for surgical therapy in the early phase of the disease. This allowed us to follow the natural evolution of the malignant tumor over 12 years. Another aspect is the favorable evolution, extremely rare in such advanced locoregional cases.

Prognostic factors for survival can be classified into anatomical, histopathological and genetic. Anatomic predictors include largest basal tumor diameter, tumor thickness, ciliary body involvement, raised intraocular pression, and extraocular spread. Histologic predictors include presence of epithelioid melanoma cells, closed loops as vascular mimicry patterns, presence of macrophages and lymphocytes, increased HLA expression, high microvascular density, high mitotic count, and loss of nuclear immunostaining for BAP1 protein (2, 3, 8). Genetic predictors for metastasis include chromosome 3 deletion, the class 2 gene expression profile, *BAP1* loss, chromosome 8q gain, chromosome 1p loss, and chromosome 9q loss, while presence of an *SF3B1* (splicing factor 3b subunit 1) mutation is associated with late-onset metastases. A class 1 gene expression profile, chromosome 6p gain, and the presence of an *EIF1AX* (eukaryotic translation initiation factor 1A, X-linked) mutations are associated with a good prognosis (8-10).

In the particular situation of our patient, no analysis of genetic factors was performed, but the risk for an unfavorable evolution is high due to the origin of the ciliary body, important extraocular extension, epithelium type, mitosis frequencies with cellular atypia and rich vascularization. The long-term prognosis remains poor due to the high risk of developing metastases in the coming years. There is a 40% risk of metastasizing to the liver, lungs or brain within 10-15 years of diagnosis of the primary tumor. No systemic therapy was associated with an evident clinical outcome for patients with advanced disease and overall survival rate remains poor (11-15).

Hepatic metastases, which occur in 95% of patients with metastatic uveal melanoma, result in death in almost all cases. Another risk factor is the possibility of a coexistent synchronous or metachronous melanoma or non-melanoma malignancy (NMM), the incidence being estimated between 8.7% and 14% in different studies (16, 17). The most common NMMs were epithelial tumors (69.4%, most commonly carcinomas of large bowel, breast and prostate) and hematologic malignancies (21.8%) (17).

To reduce the intraoperative hematogenous dissemination of the tumor, with locoregional extension over the scleral barrier, selective embolization under angiographic control of the tumor was performed. This technique is used in the therapeutic management of liver metastases of melanoma, but the results are conflicting. Some authors report a long-term tumor

regression, however, in other papers there was no increase in survival (18-24).

Regarding the direct embolization of the orbital tumor, in the literature was reported only one case of a giant tumor in a stranded patient, with metastatic disease present and severe anemia, in which selective arterial embolization performed for palliative purposes (25), led to a significant reduction in tumor volume in the coming weeks. In the present case, the embolization was completed with surgery with a curative visa, in a patient without metastatic disease present.

CONCLUSIONS

Angiographic embolization may reduce the intraoperative risk of hematogenous dissemination and improve survival in regionally advanced ocular melanomas.

The case was challenging due to increased size of the tumor, yet the predominantly lateral extension, spearing the orbital bones and intraconal space were positive factors for favorable outcome.

MULTIMODALITY IMAGING APPROACH OF HEART DISEASES

Heart diseases can be evaluated with invasive and noninvasive imaging methods. Echocardiography (transthoracic, transesophageal, 3D, contrast, and stress) is generally considered the first-line modality for cardiovascular imaging. It provides comprehensive assessment of anatomy and physiology and contributes significantly to clinical management. Cardiac magnetic resonance (CMR) imaging is already routine and well established in the diagnosis and follow-up of heart diseases and provides accurate volumetric, functional and flow analysis, is accurate with low intra- and inter-observer variability and has become the gold standard for volume and flow assessments. Unlike some other imaging modalities, quality is not affected by body habitus and it is radiation free. Presence of metallic implants or a pacemaker may represent a contra-indication to CMR but 'CMR-compatible' devices have already appeared. Occasionally, severe claustrophobia makes it impossible for a patient to undergo routine awake CMR, so sedation can be considered if CMR imaging would change the clinical management. CMR can safely be performed during pregnancy although it is general recommendation to avoid scanning during the first trimester. Multidetector CT (MDCT) assessment of cardiac diseases has increased exponentially because modern MDCT can cover large anatomic volumes with excellent spatial resolution allowing detailed evaluation of small blood vessels such as coronary arteries, pulmonary veins, collaterals, arteriovenous malformations. Acquisition time is rapid (less than 2 min) allowing patients who are unable to lie still or supine for long periods to be imaged. Pulmonary parenchymal imaging is also provided which is highly relevant for patients with pulmonary hypertension. CT is a true 3D technique, allowing more accurate measurement in all planes of dimensions and may complement assessment of mechanical heart valve dysfunction, aortic or pulmonary dissection and allows 3D visualization of abscess formation in endocarditis, and is even practical in the critically ill patient. However, CT exposes the patient to ionizing radiation and iodinated contrast agents and does not provide information on hemodynamics, flow rate, or velocity. CT can be used to acquire ventricular volumes and function but with lower temporal resolution than 2D/3D echocardiography or CMR and at the expense of additional radiation exposure. (Giovanni Di Salvo, Owen Miller et al. Imaging the adult with congenital heart disease: a multimodality imaging approach. *European Heart Journal.* https://academic.oup.com/ehjcimaging/ article/19/10/1077/ 5067134).

THE VALUE OF TELEMETRIC INTRACRANIAL PRESSURE MONITORING IN SEVERE BRAIN TRAUMA PATIENTS

THE VALUE OF TELEMETRIC INTRACRANIAL PRESSURE MONITORING IN SEVERE BRAIN TRAUMA PATIENTS (Abstract): Severe traumatic brain injury (TBI), the "silent epidemic" is a public health concern as it contributes the most to death and disability globally among all trauma-related injuries. Brain Trauma Foundation (BTF) released in 2020 the Seattle International Sever Traumatic Brain Injury Consensus Conference (SIBICC) that consist of high-quality evidence reports and three distinct treatment protocols for the management of severe TBI (sTBI). Intracranial pressure (ICP) monitoring is valuable for neurocritical care and patient outcome. The purpose of this study was to assess the outcome of 19 patients with ICP and analyze the benefits of telemetric intracranial pressure monitoring. Traumatic brain injury patients admitted to our hospital that underwent ICP monitoring with Neurovent-P-tel, an improved way of monitoring ICP and proving neurocritical care. Analyzed variables were demographics, mechanism of injury, Glasgow Coma Scale (GCS), head injury specifics, ICP measures and days of ICP monitoring. **Material and methods:** We included in the study 19 patients from our NICU (neurointesive care unit) (15 males and 4 females). Median age was 42 (75-15) years and mean days of telemetric monitoring 2 (1-8). The majority of the patients were involved in motor vehicle accidents (12), but other causes were included (4 falls, 1 assault, 1 epilepsy related, 1 unknown). **Results:** The 19 implanted telemetric sensors functioned well during the NICU admission with no documented complications. We found that ICP telemetric monitoring had benefits to the patient outcomes. **Conclusions:** In our experience, telemetric ICP monitoring is safe to use in a traumatic neurosurgical event. Larger studies need to be made in order for this method to be used as standard care. **Keywords**: TRAUMATIC BRAIN INJURY (TBI), INTRACRANIAL PRESSURE (ICP), BRAIN TRAUMA FOUNDATION (BTF), TELEMETRIC, DECOMPRESSIVE CRANIECTOMY (DC).

Traumatic brain injury is known as the "silent epidemic" as in increases the number of global mortality and disability. In European Union, the overall incidence rate of TBI is 262/100,000 (1-3). The majority of the patients with severe TBI develop elevated intracranial pressure (ICP) that causes secondary brain injury and worse outcome (4). Besides the acute phase of intracranial hypertension, patients may also

develop late onset post-traumatic hydrocephalus, which can be difficult to diagnostic in patients who still have an altered mental state or neurological deficits from the initial injury (5-7).

The historical doctrine discovered by Monroe and Kellie centuries ago regarding intracranial pressure (ICP) is the base mechanism used in present guidelines to demonstrate dysfunctional intracranial compliance. They linked ICP to a mild positive pressure created by the brain, cerebral blood volume and cerebrospinal fluid (CSF) in a semi-rigid skull box. After a traumatic brain injury brain insults can occur and disturb the normal compensation of pressure between the components (8-10).

ICP has been first introduced in the medical word by Guillaume and Janny in 1951 but recognized in traumatic standard care in 1995 in the first guidelines published by the Brain Trauma Foundation (11, 12). The current guidelines recommend continuous ICP monitoring in all salvageable severe TBI patients (Glasgow coma scale < 8) with a computed tomography (CT) scan revealing intracranial pathology or severe TBI with a normal CT scan but who exhibit two or more of the following risk factors: age over 40years, unilateral or bilateral motor posturing, or a systolic blood pressure of < 90 mmHg (13, 14).

For continuous ICP monitoring, the external ventricular drain (EVD) and intraparenchymal monitor (IPM) have been the diagnostic and therapeutic method of choice (15), but they are not without complications and limitations.

Recently, the telemetric technique was introduced to address the disadvantages of former ICP monitoring and to make long-term and less invasive monitoring more feasible (16-18). The technology has been previously used in diagnosis and treatment of patients with hydrocephalus, as postoperative monitoring after endoscopic third ventriculostomy and corrective surgery in craniosynostosis, and in research to establish reference values for normal ICP (7). Telemetric devices usually consist of three parts: the implantable sensor, reader unit or antenna, and receiver and display unit (fig. 1).

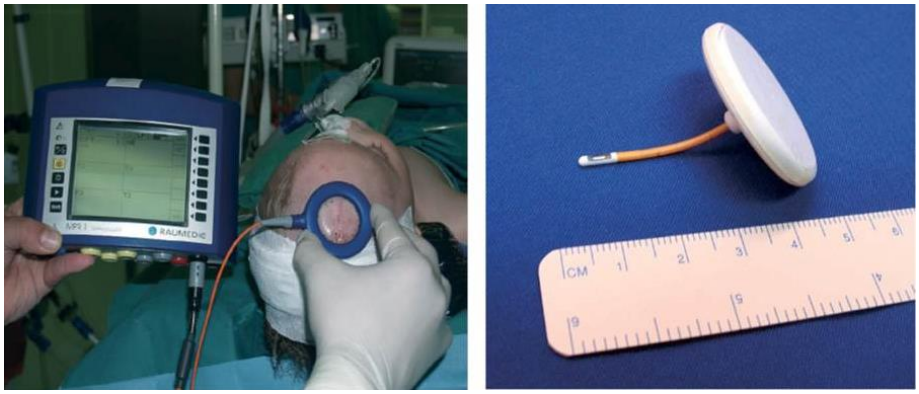

Fig. 1. Hardware for telemetric intracranial pressure monitoring; view in operating room (personal case) (left) and a close-up to the NEUROVENT P-tel Implant (right)

The purpose of this study was to assess the outcome of 19 patients with ICP telemetric monitoring that suffered a traumatic brain injury between January 2018 and

until June 2019.

MATERIAL AND METHODS

We included in our study patients with severe traumatic brain injury that required ICP monitoring with a GCS < 14 from January 2018 to June 2019. The patients underwent ICP monitoring with a telemetric device. The telemetric monitoring system consists of a passive implant sensor (Neurovent-P-tel), an active reader device (RAUMEDIC-TDT readP) and a portable recording unit (RAUMEDIC MPR1 DATALOGGER) (fig. 1). The recording device can be programmed to show different aspects of the monitoring and different alarm limits of ICP can be set. The sensor has a 5F catheter tube with a length of 25 mm, diameter of 1,7 mm, which is inserted into the brain parenchyma. The catheter is connected to a microchip enclosed in a disc-shaped ceramic housing, which is placed on the skull surface under the skin. The device is compatible with MRI scanners up to 3T. All equipment was produced by RAUMEDIC AG, Helmbrechts, Germany.

Patient demographics and clinical characteristics collected for analyzing were age, gender, GCS in admission, type of intracranial injury, mechanism of injury, ICP measures and days of ICP monitoring.

RESULTS

During the study period 19 patients met the criteria for the analysis and received ICP telemetric implant. The mean age was 42, ranging from 15 to 75 years old. The majority of the patients were males (15 patients, 78.95%) and 4 females (21.05%) (tab. I). The common cause of mechanism of injury was motor vehicle accident with 12 patients (63,16%), followed by falls with 4 patients (21.05%), 1 epilepsy related (5.26%), 1 assault (5.26%) and 1 unknown cause (5.26%) (tab. II).

GCS was measured at admission and 9 patients (47.37%) had GCS score of 3-5, 7 patients (36.84%) had GCS score of 6-8 and 3 patients (15.79%) had GCS score of 9-14. All the patients suffered from multiple brain injuries. Almost all patients had brain contusions (17 patients, 89.47%), 16 suffered from cranial fractures (84.12%), 8 had subdural hematoma (42.11%) and 4 had epidural hematoma (21.05%). From all the patients, only 2 patients underwent DC in the first 24hours and 6 patients required DC afterwards. All 19 patients were implanted telemetric ICP monitoring (tab. I).

Discharged	9 (47.37%)
Deceased	10 (52.63%)

The 19 implanted telemetric sensors functioned well during the NICU admission without wound infections or other complications observed. Mean days of ICP monitoring were 2, ranging from 8 days to 1. Measured ICP from the patients had a max of 60 mmHg, a min of 4 mmHg (mean value 16 mmHg) (tab. III). Despite our best effort 10 patients deceased (52.63%) and 9 patients survived (47.37%).

DISCUSSION

ICP monitoring is regarded as the standard care for managing severe TBI in the neurointensive care unit, although in the Brain Trauma Foundation guidelines we find is as a class III evidence (13). The rationale for this recommendation is to maintain adequate cerebral blood flow and oxygenation by preventing intracranial hypertension to remain untreated (19). The negative effects of intracranial hypertension on clinical outcome following severe TBI have been known for decades (20). Early treatment of rising ICP is known to reduce the risk of secondary brain injury and therefore improvement in overall survival and neurological functional outcome (21). ICP monitoring can not only drive intervention, but also allow for evaluation of the response to various therapeutic pressure lowering intervention (19). Our study observed the beneficial effects of ICP monitoring, that allowed the treatment with non-surgical and surgical methods when needed.

Regarding the age of the patients that sustained traumatic brain injuries, there is a direct link with the risk of mortality. Fadi al Saiegh *et al.* found that there is a 1.2 times greater risk of mortality with every 10-year-increase in age regardless of whether the patients had an ICP monitor or not (22). Areas *et al.* found that age > 65 years was an independent predictor and had 2.25 higher odds of in-hospital mortality (23). Our found also that old age had a negative impact on patients outcome.

Intracranial implants for telemetric ICP monitoring have risks related to the surgery such as intracranial hemorrhage and infections (7, 24). The patients admitted to the NICU present with coagulopathies related to either the inflammatory response of the disease (e.g., in TBI), to anticoagulant drugs (stroke prophylaxis) or secondarily to intensive care interventions (e.g., fluid resuscitation). In our study no patient experienced procedure-related hemorrhage. Antes *et al.* found punctate hemorrhages without focal deficits in 9.4% of 185 patients studied, 5.6% had larger hemorrhages without focal deficits and 0.6% had a large hemorrhage with focal deficits (18).

Similarly, NICU patients are at risk for

infectious complications due to penetrating injuries and invasive procedures for treatment and monitoring purposes. The risk of wound infection of conventional ICP monitoring ranges from 7.3% to 10.4% (7, 24) and Antes *et al.* reported a risk of wound infections of 1.1% in telemetric ICP monitoring (18). In our study population, we encountered no wound or intracranial infections related to the insertion of the telemetric ICP sensors.

CONCLUSIONS

The present study evaluated the benefits of ICP telemetric monitoring in severe TBI patients in our neurointesive care unit. Our conclusion is that telemetric ICP monitoring in an acute neurosurgical patients is safe and feasible.

Further studies are needed to evaluate the long-term use of ICP telemetric monitoring and in order for this method to be used as standard care.

COVID-19 A CHALLENGE FOR DENTISTS?

After COVID-19 was declared a pandemic by the World Health Organization, dentists were instructed by regulatory authorities to stop the services except the emergency. Dentists are among the highest risk categories for transmission and contraction of the coronavirus, with many routine dental procedures having the potential to transmit the virus through aerosols. This was mainly for protection of dental healthcare personnel, their families, contacts, and their patients from the transmission of virus. Most dental procedures generate aerosol; preparing cavities for fillings, use of rotary instruments for root canal treatment, scaling and polishing of teeth, dental implantation and surgical removal of teeth are only some examples. Researchers should focus on developing barrier techniques and negative pressure procedures to contain and isolate the aerosol so that dental procedures to be safe for dental healthcare personnel and patients alike. (Najla Dar Odeh, *et al.* COVID-19: Present and Future Challenges for Dental Practice. *Int J Environ Res Public Health* 2020; 17(9): 3151).

CONCOMITANT LAPAROSCOPIC HIATAL HERNIA REPAIR WITH CHOLECYSTECTOMY: A MULTICENTRIC STUDY (Abstract): Concomitant surgery refers to performing two or more surgical operations on one patient under the same anesthesia. **Material and methods:** We performed a retrospective multicenter study from October 2016 to October 2019, analyzing patients who underwent laparoscopic hiatal hernia repair. We extracted data of patients who underwent concomitant laparoscopic surgery for both hiatal hernia repair and cholecystectomy in the following Clinics: 1st Clinic of Surgery of Craiova Emergency Clinical County Hospital, "Colţea" Hospital, 3rd Clinic of Surgery of Cluj-Napoca and 3rd Surgery Clinic of University General Hospital of Thessaloniki and identified 20 patients who underwent hiatal hernia repair and had an added cholecystectomy. **Results:** Allocation of data by hiatal hernia type showed 6 type IV hernia (complex hernia), 13 type III hernias (mixed type) and 1 type I hernia (sliding hernia). Out of the 20 cases analyzed; 19 were chronic cholecystitis and one patient presented with acute cholecystitis. Average operating time was 168 minutes. Blood loss was minimum. Crurorraphy was performed in all cases, mesh reinforcement was added in 5 cases, and fundoplication was added in all cases: 3 Toupet, 2 Dorr and 15 Floppy-Nissen. Fundopexy was routinely added in cases with Toupet fundoplication. Cholecystectomy was performed in the following manner: 19 retrograde, 1 bipolar. All patients had favorable postoperative course. Patients follow up was at 1 month, 3 months and 6 months, with no signs of recurrence for hiatal hernia (anatomical or symptomatic) and no post cholecystectomy syndrome. **Conclusions:** Concomitant laparoscopic hiatal hernia repair and cholecystectomy is a safe and feasible option for patients with indication of surgery for both pathologies. **Keywords:** HERNIA, HIATAL, TOUPET, DORR, FLOPPY-NISSEN, CHOLECYSTECTOMY, CONCOMITANT.

Laparoscopic surgery is the golden standard for both hiatal hernia repair and cholecystectomy and offers fast recovery time with less operative time and is both

safe and effective (1). Type I hiatal hernias with impact on quality of life and refractive to medication, type II, III and IV symptomatic hiatal hernia have indication for surgery (2).

Concomitant surgery refers to performing two or more surgical operations on one patient under the same anesthesia. With the quick and widespread adoption of laparoscopic approach in surgery, the emergence of concomitant surgery has seen a rapid incline in the number of cases. It has been almost three decades since laparoscopic approach has become the gold standard for cholecystectomy (3) and the standard for hiatal hernia repair today is also by laparoscopic approach (2). Laparoscopy is not the standard for all surgical interventions, but considering that the minimally invasive approach for both hiatus hernia and cholecystectomy is the standard of care, concomitant surgery has its charm. The idea that you can combine multiple minimally invasive surgeries and perform them under one anesthesia is very appealing, as in open surgery, plus the advantages of minimal invasively: decrease in postoperative hospitalization, decrease in analgesic use, early recovery (when compared to procedures performed at different times), and increase in patient satisfaction. However we should take into account the prolongation of operative time, risk for both intraoperative complications and postoperative morbidities for both interventions.(4)

MATERIAL AND METHODS

We performed a retrospective multicenter study from October 2016 to October 2019, analyzing patients who underwent laparoscopic hiatal hernia repair.

We extrapolated data of patients who underwent concomitant laparoscopic surgery for both hiatal hernia repair and cholecystectomy in the following Clinics: 1st Clinic of Surgery of Craiova Emergency Clinical County Hospital, "Colțea" Hospital, 3rd Clinic of Surgery of Cluj-Napoca and 3rd Surgery Clinic of University General Hospital of Thessaloniki. We collected data regarding demographics, comorbidities, imaging, operative time, blood loss, intraoperative complications, postoperative evolution and follow-up. Values were imported into *Microsoft Excel* (Microsoft Office) and analyzed.

Patients presented indication for surgery for both hiatal hernia repair and cholecystectomy. In this study, no patient with completely asymptomatic gallbladder lithiasis was included.

For the diagnosis of hiatal hernia one or more of the following were performed: upper digestive endoscopy, oral and intravenous contrast enhanced computed tomography and upper digestive endoscopy. Preoperative Visick score for reflux disease was at least three. Gallbladder lithiasis was diagnosed with abdominal ultrasound.

Preoperative, all patients underwent deep venous thrombosis (DVT) and pulmonary embolism (PE) prophylaxis with *low molecular weight heparin*, bowel preparation with anti-foaming agents to reduce bloating and *nil per os* at least 12 hours before surgery.

Interventions were performed under general anesthesia, with endotracheal intubation for all patients. All patients were placed in Trendelenburg French position, both arms tucked along the upper body.

RESULTS

We identified 20 patients who underwent laparoscopic hiatal hernia repair and cholecystectomy in the same operative time.

Mean age was 63 years-old, median of 65 years, minimum of 46 years old, maximum of 75 years old and standard deviation was 7.2 years. All patients were female, and one out of 20 patients was admitted through emergency setting, while the rest were elective.

Case distribution by age group is shown in first figure.

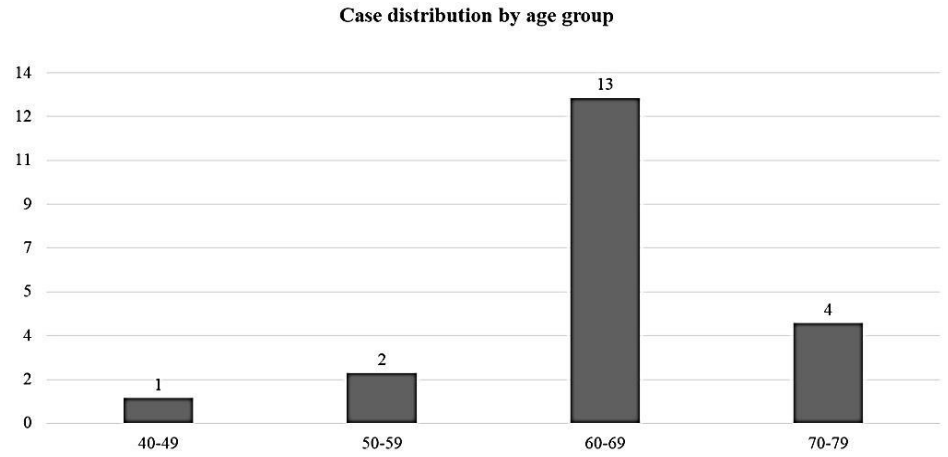

Fig. 1. Case distribution by age group is shown

Four patients (20%) were from a rural area, while 16 patients (80%) were from an urban area. Allocation of data by hiatal hernia type showed 6 type IV hernia (complex hernia), 13 type III hernias (mixed type) and 1 type I hernias (sliding hernia) (fig. 2). Out of the 20 cases analyzed, 19 were chronic cholecystitis and one patient presented with acute cholecystitis (fig. 3).

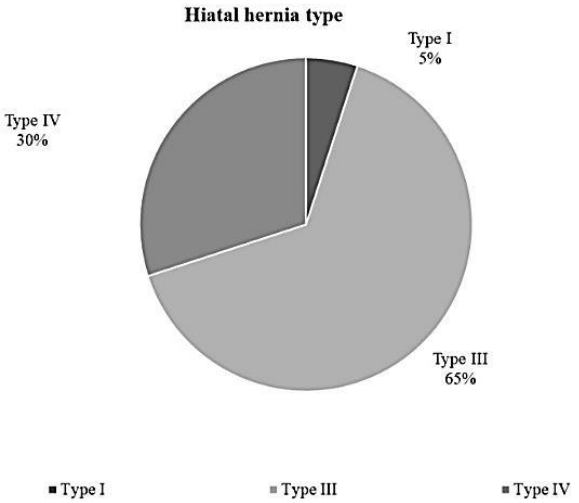

Fig. 2. Hernias type distribution

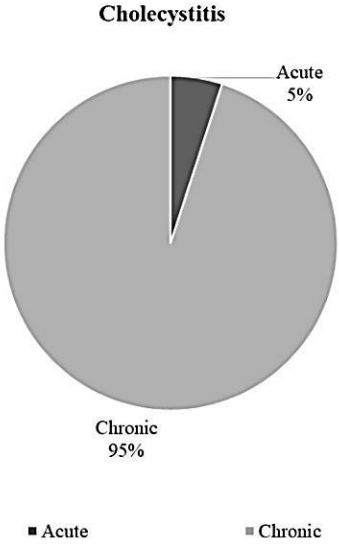

Fig. 3. Cholecystitis type

The most frequent comorbidities were obesity (10 patients) and hypertension (17 patients). Most frequent symptom was heartburn, present in 18/20 patients (90%) with a symptom duration ranging from 1 year to 20 years, under proton pump inhibitor medication, with partial symptom cessation. Regurgitations were present in 13 patients the average duration of symptoms was one year. Pain was the second most prevalent symptom and if ordered by location frequency it was: epigastric (50%); left hypochondrium (33.3%), left hemi-thorax (25%) and retrosternal pain (16.66%). Pain was postprandial in 9 patients (45%), while lying down in 7 patients (35%), ceased after eructation in 4 patients (20%) and referred pain in the left shoulder in 4 patients (20%). Other presenting symptoms with a lower incidence were dysphagia 4 cases, anemia 5 cases, coughing 5 cases (fig. 4).

The performed imaging, by order of frequency were upper digestive endoscopy (85%), barium meal (60%) and computed tomography (20%) (fig. 5).

Access in the peritoneal cavity was achieved through insufflation by Veress needle in 17 cases, 3 cases with optical access; regarding the insufflation point: 14 supra-umbilical, 6 Palmer point, with no insufflation incidents.

Average operating time was 168 minutes, median 180 minutes, minimum 120 minutes, and maximum 210 minutes. Blood loss was minimum. Crurorаphy was performed in all cases, mesh reinforcement was added in 5 cases, and fundoplication was added in all cases: 3 Toupet, 2 Dorr and 15 Floppy-Nissen. Short gastric vessels of the fundus were divided in all cases, for better mobilization. Wrap height varied between 2-3 centimeters. Fundopexy was routinely added in cases with Toupet fundoplication. Cholecystectomy was performed in the following manner: 19 retrograde, 1 bipolar. Drainage for gallbladder was added in 16 cases and was kept in place for 1-5 days. Nasogastric aspiration tube was not maintained in the postoperative period.

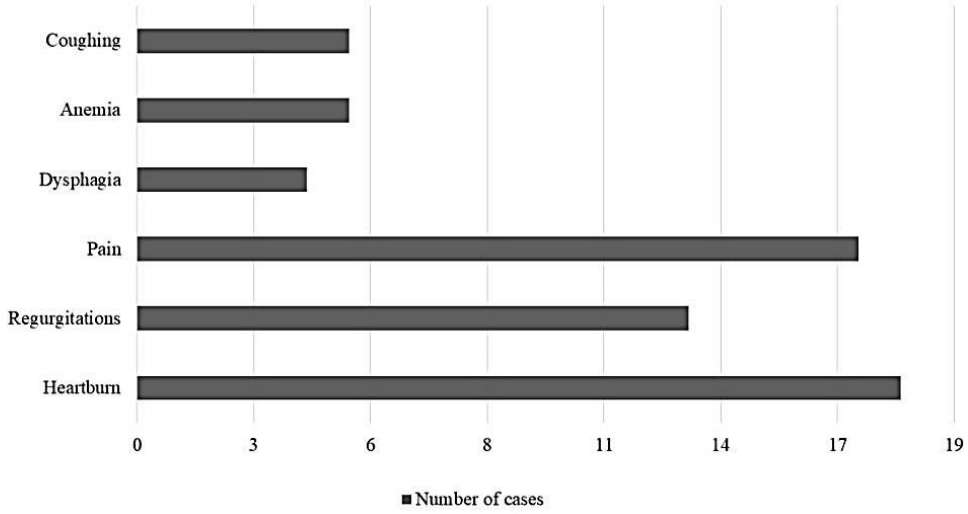

Fig. 4. Presenting symptoms

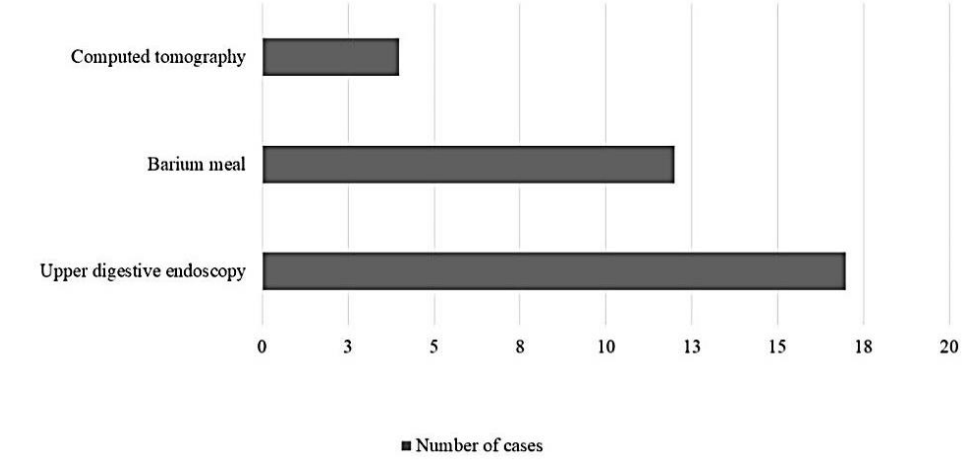

Fig. 5. Performed imaging, by order of frequency

Three patients stayed overnight in the intensive care unit. All patients had favorable postoperative course, started active mobilization by postoperative day 1, passage of flatus by postoperative day 2 and had a stool emission by discharge.

Postoperative discharge was between POD 3 and POD 9, average of 5.5 days, median 6 days. Opioid analgesics were used only during anesthesia, broad spectrum intravenous antibiotic was given intraoperatively for all patients at anesthesia induction and only one patient with acute cholecystitis received broad spectrum intravenous antibiotic 4 days. Postoperative pain management was achieved by non-opioid analgesia on demand of the patient. Pain was measured preoperatively, postop-

eratively and at 1-month follow-up using the Pain visual analogue scale (VAS) preoperative (fig. 6).

Patient follow-up was at 1 month, 3 months and 6 months, with no sign of recurrence for hiatal hernia (anatomical or symptomatic) and no minor complaints of post cholecystectomy syndrome, like fullness or dullness in the upper right quadrant, especially after some movements.

	0	1	2	3	4	5	6	7	8	9	10
1 month follow up	1	10	7	2	0	0	0	0	0	0	0
Postoperative	0	0	3	5	6	5	1	0	0	0	0
Preoperative	0	0	0	0	2	3	5	5	3	2	0

DISCUSSION

With the increase in safety and experience of laparoscopic surgery, the desire to perform more than one operation under one anesthesia has risen in order to take advantage of the benefits of minimally invasive surgery (4, 5). Performing both hiatal hernia repair and cholecystectomy through laparoscopic approach is feasible and safe, and by performing both surgeries under one anesthesia the need for a second hospitalization is minimized, quality of life is improved, patient has no need to take multiple work break (6).

The combined procedure needs no supplementary trocar insertion other than that for hiatal hernia repair, as trocar positioning resembles the French technique for cholecystectomy. An experienced surgeon who regularly performs hiatal hernia repair should meet no impediment in combining both surgeries, even in the presence of comorbidities such as obesity. The decision to perform this combined surgery must stem from the indications for surgery for both pathologies.

Trocar insertion must be planned beforehand, with ergonomy and triangulation for laparoscopic knot tying and suturing kept in mind. In morbidly obese patients, we must bear in mind that the umbilicus is not a reliable landmark and positioning of the landmark should be at 15 centimeters from the xiphoid on the xipho-umbilical

line (7).

Imaging plays a paramount role and should not be discredited by the desire to reduce costs, as the importance of the findings can play a vital role in the indication for surgery, procedure used and planning. Upper digestive endoscopy, the most performed investigation in our study for hiatus hernia can not only diagnose hiatal hernia but also esophagitis, Cameron ulcers and other benign or malign coexisting pathologies and can lead to a decision for surgery. Upper digestive endoscopy, in the hands of an experienced endoscopist can even rise the suspicion of a parahiatal hernia which can be confirmed by barium meal (8).

Barium meal is the gold standard for diagnosing hiatus hernia and it brings the benefit of excellent visualization of hernia sac and provides orientation for the surgeon. It was not the most performed investigation in our study, as we believe that if endoscopy provides large sizes of the hernia (large enough to classify it as a type 3), or if a type 2 paraesophageal hernia is present, barium meal is no longer mandatory. Barium meal offers a very good visual representation of the herniated stomach but is lacking in cases of complex hernias in which other abdominal organs are herniated. Computed tomography (CT) should not be overlooked as it has the potential to provide the most information, especially if enhanced with intravenous and oral contrast. It can diagnose both gallbladder stones, choledocholithiasis and all types of hiatus hernia; it can provide a better understanding of the particular anatomy of every patient. With the emergence of tridimensional reconstruction software and preoperative planning software, CT can bring a vital role in surgical planning of trocar positioning for better ergonomy for the surgeon, decreased blood loss and operating time.

Performing both surgeries provides the evident benefit of one anesthesia and one surgical time for two pathologies and is both safe and feasible in the hands of an experienced laparoscopic team (4). Operating time was 168 minutes compared to the average operating time of the standalone hiatal hernia repairs, which was 148 minutes. Operating time is similar with standalone surgery and blood loss was minimum in both cases. Oral intake, bowel movement and active mobility resumption was similar with standalone hiatal hernia surgery.

Although evidence exists regarding safety in placing mesh in clean-contaminated cases (9-14), we believe that the current level of evidence is not high enough and we advise use of mesh only in carefully selected cases if cholecystectomy is performed.

We must not forget the dreaded complications meshes can produce and we believe that it should only be used as a last resort, in cases where crural appropriation is not possible or in selected cases of recurrent hiatal hernia.

Regarding the order of the interventions, the hiatal hernia is usually performed first and then the cholecystectomy. For surgeons who regularly operate between the patients legs, the transition is easy, but for surgeons who perform hiatal hernia repair from the right side of the patient, the transition is more difficult, having to change the position of the laparoscope.

Common bile duct injuries are the Achilles heel in laparoscopic surgery versus open surgery with reported rates being higher in the laparoscopic group (14-20). Although laparoscopic cholecystectomy is

a relatively common and simple procedure, the surgeon is performing it after a hiatal hernia repair, which can lead to fatigue. The surgeon should be in a familiar position for cholecystectomy, with good operative view, good ergonomy and should bear in mind the risk of this injury especially if fatigued. Both procedures can be accompanied by intraoperative incidents and accidents, which can lead to severe morbidity. If a post cholecystectomy syndrome is suspected in the postoperative period, a careful evaluation of the patient must also include suspicion of hiatal hernia recurrence.

CONCLUSIONS

In conclusion, concomitant laparoscopic hiatal hernia repair and cholecystectomy is a safe and feasible option for patients with indication of surgery for both pathologies.

NEWS

THE BENEFITS FOR PATIENTS WITH INFLAMMATORY BOWEL DISEASE TAKING ASCVD MEDICATIONS

Chronic inflammation in patients with inflammatory bowel disease (IBD) leads to increased risk of atherosclerotic cardiovascular disease (ASCVD). The incidence of ASCVD is increased in patients with IBD as reported by multiple population-based and few retrospective case control studies. Numerous studies have examined an overlap in treatment between IBD and heart disease, with relative success. A retrospective matched case–control study (Ungaro *et al*.) assessed statin use in patients with IBD. Statin use was associated with a significantly decreased risk of IBD. In addition to studies showing benefit for patients with IBD taking ASCVD medications, there have been studies assessing the role of anti-inflammatory medications for ASCVD in the general population. In a multicenter randomized control (CANTOS) trial (Ridker *et al.*), canakinumab, a human monoclonal antibody targeted at IL-1, showed a 15% reduction in deaths from heart attacks and strokes combined. A nationwide retrospective cohort study noted that for patients with IBD taking 5-aminosalicylic acid (5-ASA), the incidence of IHD was significantly less compared to those not taking 5-ASA. Clinicians should be aware of the harmful effects of chronic inflammation on the heart. ASCVD risk is increased among patients with IBD especially during periods of active disease. (Weissman S, Sinh P, Mehta TI, *et al.* Atherosclerotic cardiovascular disease in inflammatory bowel disease: The role of chronic inflammation. *World J Gastrointest Pathophysiol* 2020; 11(5): 104-113).

CONSISTENCIES AND INCONSISTENCIES OF GLEASON SCORE AND GRADE GROUP SYSTEM IN PROSTATE BIOPSY AND RADICAL PROSTATECTOMY

CONSISTENCIES AND INCONSISTENCIES OF GLEASON SCORE AND GRADE GROUP SYSTEM IN PROSTATE BIOPSY AND RADICAL PROSTATECTOMY (Abstract): The diagnostic of prostatic adenocarcinoma (PADK) is based on two scoring systems, namely the Gleason grading system and the grade group system - both of them being included in the pathology report. There is a discrepancy in the Gleason score given on the initial biopsy and prostatectomy specimen, respectively, that affects both patients who can benefit from active surveillance and those who cannot benefit from curative surgical treatment, and for whom therapeutic alternatives must be established. In this context, our study aimed at analyzing the diagnostic concordance between biopsies and subsequent prostatectomies, in order to establish the accuracy of prostate biopsy in predicting final Gleason score of the prostatectomy specimens. **Material and methods:** We analyzed 79 cases of PADK, initially diagnosed by prostate biopsy and subsequently treated by radical prostatectomy. The accuracy degree of the tumoral grading system assigned to the prostate biopsy, compared with the radical prostatectomy, was assessed by calculation of the Cohen's kappa concordance coefficient and calculation of sensitivity, specificity, positive prognostic value and negative prognostic value. **Results:** 37 cases (46.83%) presented the same Gleason score given for prostate biopsies and radical prostatectomies. In prostate biopsies, 32 cases (40.50%) were underestimated, compared to the Gleason score established by evaluating radical prostatectomy specimens, and 10 cases (12.65%) were overestimated. The highest agreement rate between the Gleason score in prostate biopsy and radical prostatectomy was found for Gleason score 6 (3+3) and 7 (3+4)-17 cases (21.51%) for each score category. The lowest agreement rate was observed for Gleason score 5, where no case showed a similar score for biopsy and prostatectomy. Statistical analysis indicated a kappa coefficient of 0.23, corresponding to a statistically significant satisfactory agreement ($p = 0.01$). The agreement on ISUP prognostic grade groups between prostate biopsy and radical prostatectomy indicated a slight increase in kappa coefficient -0.41, while maintaining a statistically significant moderate agreement ($p = 0.0001$). **Conclusions:** Our results demonstrate an increase in the predictive accuracy of prostate biopsy, as a result of the application of prognostic grade group system, which ensure the decrease of overestimating tendency of the old scoring system, ultimately leading to a preliminary characterization of potential lesions in prostatecto-

my specimens and a more effective treatment stratification of patients. **Keywords:** PROSTATIC ADENOCARCINOMA, GLEASON SCORE, PROGNOSTIC GRADE GROUP, PROSTATE BIOPSY, RADICAL PROSTATECTOMY.

The diagnosis of prostatic adenocarcinoma (PADK) is based on a combination of well-defined microscopic architectural, cytological and immunohistochemical features. Apparently, the microscopic identification of this neoplasia seems quite simple. However, pathologists, in their current practice, confront difficulties in recognizing and classifying histological subtypes, in line with the classification benchmarks for this pathology, which have undergone important updates in the last decade (1, 2).

The milestone in PADK diagnosis is represented by the Gleason grading system proposed by Donald Gleason in 1966 as Gleason score and constantly changed up to 2005 as a result of diagnostic experience and research on the relationship between histological, clinical and prognostic parameters (3-6). In 2005, the modified variant of the Gleason score was implemented (7), which became the most important diagnostic and prognostic tool of the PADK between 2005-2014, playing a decisive role in establishing and managing oncological and surgical protocols and in active monitoring (8-10).

The Gleason grading system modified in 2005 increased the diagnostic reproducibility and provided a better correlation between the Gleason score assigned on prostate biopsies and the final Gleason score attributed to the prostate resection specimen (11-13).

In the face of continuously accelerating scientific advancement in the medical field, under the motivation of improving the Gleason scoring system and solving its limitations, in 2014 the International Society of Urologic Pathology (ISUP) Consensus Conference validated a new prostate neoplasm grading system (2). This new prognostic grade group system is directed to the more precise stratification of prostate lesions in relation to the prognostic dictated by Gleason scoring. The five prognostic grade groups were established by reference to the probability of 5-year biochemical recurrences free progression following radical prostatectomy.

Currently, as recommended in 2016 WHO Classification for tumors of the urinary system and male genital organs (1), diagnostic evaluation of PADK is based on two scoring systems, namely the Gleason grading system and the grade group system -both of them being included in the pathology report.

A major issue on which the interest of pathologists focuses is the assessment of the discrepancy recorded in the Gleason score given on the initial biopsy and prostatectomy specimen, respectively. According to the literature, this discrepancy is present in about 50% of cases, in general the grading on the prostatectomy specimen being higher compared to the biopsy (14-17). Differences in PADK grading, in prostate biopsy and prostatectomy specimen, are important because they indicate the possibility of an underestimation or overestimation of diagnosis and implicit prognosis. This affects both patients who can benefit from active surveillance and those who cannot benefit from curative surgical treatment, and for whom therapeutic alternatives must be established.

In this context, our study aimed at analyzing the diagnostic concordance between biopsies and subsequent prostatectomies, in order to establish the accuracy of prostate biopsy in predicting final Gleason score of the prostatectomy specimens.

MATERIAL AND METHODS

The study group included 79 cases of PADK, diagnosed between January 2010 and December 2018 within the Department of Pathology of the Clinical Hospital "Dr. C.I. Parhon" Iași. Patients were initially diagnosed by prostate biopsy and subsequently treated by radical prostatectomy.

The study was approved by the Research Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy, Iași.

A number of 6, 12 or 24 tissue fragments were taken by ultrasound-guided prostate biopsy from both prostate lobes. In all cases, the Gleason score was assigned according to the Gleason grading system adopted by WHO in 2016 (1) and was completed by ISUP grading classification in groups (2). The cases in the grade groups 1 and 2 were considered low grade cases, those in the grade group 3 as moderate grade, and those in grade groups 4 and 5 as high grade. Under-evaluation was defined as assigning a lower Gleason score on prostate biopsy compared to the one set on the subsequent radical prostatectomy specimen, while overestimation consisted of a higher initial Gleason score on prostate biopsy.

To assess the accuracy degree of the tumoral grading system assigned to the prostate biopsy, compared with the radical prostatectomy, we applied two statistical methods: calculation of the Cohen's kappa concordance coefficient with the following interpretations: values $\leq$ 0.2 -poor agreement; values from 0.21 to 0.40 -satisfactory agreement; values from 0.41 to 0.60 - moderate agreement; values from 0.61 to 0.80 -good agreement; values above 0.8 - very good agreement; calculation of sensitivity, specificity, positive prognostic value and negative prognostic value. All data obtained were considered significant for values of $p<0.05$.

RESULTS

The most common Gleason score given on prostate biopsy fragments was 6 (3+3) in 41 cases (51.89%), followed by Gleason score 7 (3+4) in 26 cases (32.91%), while on radical prostatectomy specimens the most common was Gleason score 7 (3+4) in 37 cases (46.83%), followed by Gleason score 6 (3+3) in 22 cases (27.84 %). A number of 37 cases (46.83%) presented the same Gleason score given for prostate biopsies and radical prostatectomies, respectively. In prostate biopsies, 32 cases (40.50%) were underestimated, compared to the Gleason score established by evaluating radical prostatectomy specimens, and 10 cases (12.65%) were overestimated.

The highest agreement rate between the Gleason score attributed to prostate biopsy and that of radical prostatectomy was reported in cases evaluated with Gleason score 6 (3+3) and 7 (3+4) -17 cases (21.51%) for each score category. The lowest agreement rate was observed in cases with a Gleason score 5, where no case showed a similar score for biopsy and prostatectomy. The many cases that were underestimated (19 cases - 24.05%) belonged to the subgroup with Gleason score 6 assigned to prostate biopsy, in 16 cases being established, on the prostatectomy specimen, the Gleason score 7 (3+4), and in 3 cases - the Gleason score 8 (4+4) (tab. I).

TABLE I

Concordances and Differences between Gleason Score in Prostate Biopsy and Radical Prostatectomy

GLEASON SCORE - RADICAL PROSTATECTOMY	GLEASON SCORE - PROSTATE BIOPSY (#)						Total
	5	6	7 (3+4)	7 (4+3)	8	9	
5	**0**	5	1	0	0	0	6
6	3	**17**	2	0	0	0	22
7 (3+4)	3	16	**17**	1	0	0	37

9	0	0	3	0	1	**0**	4

- number of cases

Statistical analysis to assess the accuracy of the Gleason score given on prostate biopsy fragments in predicting the Gleason score given on the prostatectomy specimen indicated a kappa coefficient of 0.23, corresponding to a statistically significant satisfactory agreement (p = 0,01). The calculation of the kappa coefficient was based on the indicators of expected coincidence, with a value of 24.46, and observed coincidence, with a value of 37 (37 cases with the same Gleason score in prostate biopsy fragments and radical prostatectomy specimens).

By analyzing the sensitivity, specificity, positive and negative predictive values in assessing the degree of accuracy of prostate biopsy scoring in predicting the final Gleason score on the radical prostatectomy specimen, we observed the following (tab. II):

- the lowest sensitivity value of 0% was reported in prostate biopsies with Gleason score 5;

- the highest sensitivity value of 77.2% was reported in prostate biopsies with Gleason score 6;

- prostate biopsies with Gleason score 5 had zero positive predictive value, while prostate biopsies with Gleason score 7 (4+3) had the highest positive predictive value -66.6%;

- the highest specificity -100% was identified for prostate biopsies with Gleason score 9, and the lowest specificity -57.8% was calculated for prostate biopsies with Gleason score 6;

- tumors with Gleason score 8 on prostate biopsy showed the highest negative predictive value -97.36%, while prostate biopsies with Gleason score 7 (3+4) showed the lowest negative predictive value - 62.2%.

The agreement on the diagnostic classification in the ISUP prognostic grade groups, according to the initial diagnosis based on the aspects identified in prostate biopsies and radical prostatectomy specimens, respectively, indicated a slight increase in kappa coefficient -0.41, while maintaining a statistically significant moderate agreement (p = 0.0001). The calculation of the kappa coefficient was based on the indicators of expected coincidence, with a value of 60.59, and observed coincidence, with a value of 68 (68 cases with the

same classification in the ISUP prognostic grade groups in prostate biopsy fragments and radical prostatectomy specimens, according to the Gleason score) (tab. III).

TABLE III

Concordances and Differences between the Prognostic Grade Groups established for Prostate Biopsy and Radical Prostatectomy

ISUP GRADE GROUP - RADICAL PROSTATECTOMY (#)	ISUP GRADE GROUP -PROSTATE BIOPSY (#)			
	1-2 (low grade)	3 (moderate grade)	4-5 (high grade)	Total
1-2 (low grade)	**64**	1	0	65
3 (moderate grade)	4	**2**	1	7
4-5 (high grade)	5	0	**2**	7
Total	73	3	3	79

- number of cases

The analysis of agreement between the prognostic grade groups established according to the Gleason score for prostate biopsies and, respectively, for radical prostatectomy specimens revealed the following aspects:

- out of the 73 cases included in the prognostic grade groups 1 and 2 in prostate biopsies, considered as low-grade cases, 9 cases (12.32%) were included in a higher-grade group after radical prostatectomy, as follows: 4 cases were classified in grade group 3, and 5 cases in grade group 4; the other 64 cases (87.67%) maintained the same prognostic grade group;

- out of the 3 cases included in the prognostic grade group 3 in prostate biopsies, considered with a moderate grade, only one case (33.3%) was re-included in the prognostic grade group 2 post surgery; for two cases, the classification was maintained;

- out of the 3 cases included in the prognostic grade groups 4 and 5 in prostate biopsies, regarded as high-grade cases, only one case (33.3%) was re-included in

the prognostic grade group 3 on prostatectomy; for two cases, the classification was maintained.

Following these permutations, the comparative analysis of the agreement of prognostic grade group classification indicated a tendency of higher grading in cases from the prognostic grade groups 1-2, reclassified in the grade group 3; a lower framing tendency, for cases from grade group 3, respectively the grade groups 4-5, reclassified in the lower grade groups.

DISCUSSION

Gleason grading system and grade group system are reference tools in the prognostic evaluation of PADK, and therapeutic decisions are dictated by their use in the diagnosis of tissue fragments obtained by prostate biopsy.

The differences between the grading of the biopsy fragment, and that of the prostatectomy specimen have as morphological substrate the multifocal feature of PADK, which determines different grading in distinct foci of the tumoral tissue. This reality may explain the oscillating rate of reported agreement between the score in prostate biopsy and radical prostatectomy with curative intent, respectively. Changes in the Gleason grading system and the introduction of the grade group system had direct implications on the concordance degree and the predictive value of the prostate biopsy, in relation to the final prostatectomy specimen.

However, the agreement rate reported in the literature is extremely variable, reflecting not only the interobserver variability, but also the different level of experience of the pathologist providing the diagnosis.

Consequently, it is imperative to validate refined criteria to ensure a high degree of accuracy and concordance between the histological grading of the biopsy and radical prostatectomy specimens. With this desideratum in mind, the efforts of specialists are also focused on identifying the factors responsible for these differences and on a better understanding of their dynamics, with the ultimate goal of reducing or even eliminating them.

Currently, routine prostate biopsy consists in 12 tissue samples, which have replaced the traditional sextant by adding biopsies of the lateral sites, thus increasing the sensitivity of prostate cancer detection. The pathology report of prostatic biopsies should include, in addition to concise description of the lesion, the percentage of tumor infiltration in each tissue fragment (expressed in millimeters or percentage), the proportion of the tumor component with the higher Gleason pattern (Gleason 4, 5), the number of tissue fragments identified with cancer, as well as their location (conditioned by sending fragments in separate containers by the clinician), the presence of perineural and capsular invasion. Numerous studies emphasize the importance of these quantitative aspects (18, 19), concluding that reporting of these parameters and grading of biopsy are indirect evidence for tumor stage and, implicitly, for tumor extension.

The extended biopsy protocol is more sensitive in detecting prostate cancer than the sextant method. In the absence of clear standardized reporting rules, some pathologists describe each biopsied tissue fragment separately, with the final pathology report including 12 Gleason scores, one score for each analyzed tissue fragment, while other pathologists prefer a general characterization of all biopsied fragments, generating a single final Gleason score

(19). These different approaches in reporting the Gleason score on prostate biopsy (in relation to the number of positive fragments and the percentage of tumor lesions) are variables with important implications in the therapeutic management of the patient.

In this regard, published studies in the literature (20-22) indicate that the highest Gleason score among the individual Gleason scores attributed partly to each biopsied tissue fragment is better correlated with the Gleason score assigned to radical prostatectomy, compared to an overall Gleason score reported for all tumor-positive prostate fragments.

Considering the possibility of multiple tumor foci with heterogeneous morphological characteristics (23), recent studies recommend the linear measurement of discontinuous tumor foci, as a more accurate method in predicting the degree of aggressiveness and tumor extension on the radical prostatectomy specimen, being better correlated with higher tumor stages (24).

How to report the percentage of a Gleason pattern 4 on prostate biopsy fragments remains a matter of controversy, given the significant link between the high incidence of Gleason pattern 4 in cases with a final Gleason score 7 on the prostatectomy specimen and high risk of disease recurrence (25). The estimation of the tumor component with Gleason 4 pattern on prostate biopsy shows interobserver variability, regardless of the used method (visual or digital), with important impact on therapeutic decision (26). However, numerous studies support the need to integrate it into the pathology report, given that the cribriform architecture (currently considered as Gleason pattern 4) is related to an adverse prognostic, at higher risk of biochemical recurrence (27) and metastatic disease (28). At the same time, reporting the percentage of Gleason pattern 4 on prostate biopsies in a final Gleason score 8 (ISUP grade group 4) on radical prostatectomy was found to be related to an increased risk of visceral and bone metastasis (29).

In addition to the lack of standardization of prostate biopsy reporting, three other major factors may be responsible for discrepancies between the Gleason score established on prostate biopsies and the final Gleason score attributed to radical prostatectomy: proportion of tumor tissue on biopsied tissue fragments, variable histopathological interpretation and sampling defects (30).

Our study revealed an agreement rate of the Gleason score in prostate biopsy and radical prostatectomy specimen of 46.83%; 40.50% of cases were underestimated and 12.22% of cases were overestimated. The accuracy rate was 0.23, corresponding to a statistically significant satisfactory agreement ($p = 0.01$). The highest agreement rate, 54.5%, was achieved in the Gleason score 7 category (3+4), while in Gleason score 6 we reported a concordance of only 44.2%. The achieved results indicated the main score change introduced by 2016 WHO classification, which is the classification of cribriform and glomeruloid architecture as Gleason pattern 4. This change led to an increase in the number of cases diagnosed with score 7 (3+4 and 4+3). Given that these aspects are relatively easy to identify by microscopic examination, a recent study indicates a sensitivity of 56.5% and a specificity of 87.29% in the recognition of cribriform pattern in prostate biopsy (31). Moreover, the use of ISUP prognostic grade groups corresponding to Gleason scores led to an increase in kappa

coefficient calculated up to the limit of 0.41 -which has a moderate agreement rate.

Our data complete the general framework of reporting in the literature, the values obtained being in line with the recognized scale of values. To support this statement, we consider it appropriate to briefly review the data on the diagnosis agreement between prostate biopsy and radical prostatectomy.

Studies published before 2014 - which marked a new age by changes to the Gleason grading system and introducing grade group system -show agreement rates of 41% (32), 43% (30), and 53% (33). The results were more often under-graded (34% or 38%) than over-graded (9%) (33, 34); 80% of cases diagnosed with unilateral disease on biopsy presented bilateral involvement in prostatectomy specimens (34). The agreement in Gleason score between biopsy and radical prostatectomy was highest among the uropathology departments that general pathology ones (33), and the accuracy of the prostate biopsy increased when at least eight cores were analyzed (34). On the other hand, the results of a much broader meta-analysis (analyzing over 14,000 cases) conducted in 2008 indicate a much higher percentage for concordance and overestimation -63% and 30%, respectively, and a lower percentage for underestimation -7% (35). The same meta-analysis stratifies the histopathological diagnosis into 3 categories, namely cases with low tumor grade, moderate tumor grade and high tumor grade, and reports the following concordances: 62% for low tumor grade, 70% for moderate tumor grade and 50% for high tumor grade (35). The accuracy of the diagnostic classification was quantified by the kappa coefficient, obtaining a value of 0.37, corresponding to a satisfactory agreement (35). Also in 2008, a study based on a much smaller number of cases (just over 1000) supports an agreement rate of 81% for Gleason score 5-6, 68% for Gleason score 7 and 70% for Gleason score 8-10 (36).

Studies published after 2016 indicate a higher level of concordance, with values of 54.5% (37), 55.4% (38), 59.3% (39), 62.5% (40) and 63.2% (41). There is also a higher rate of upgraded cases than of downgraded cases (31.1% versus 14.3%) (37). Using the population-based Surveillance, Epidemiology, and End Results (SEER) database, with a total number of 34,195 analyzed patients, Wong *et al.*, 2017 report a kappa coefficient value of 0.36, indicating a fair agreement with the following features: in Gleason score 6 the concordance was 55.3%, with 43.1% cases upgraded to Gleason score 7; in Gleason score 7, the concordance was 66.9% for 7 = 3+4 and 42.9% for 7 = 4+3; in Gleason score 8 the concordance was 24.8%, with a downgrade rate of 57.4% (38).

The level of concordance depending on the grade group is variable, the values reported being: 47.6% for group grade 1, 73.6% for group grade 2, 52.8% for group grade 3, 21.4% for group grade 4 and 68.3% for group grade 5, with upgrade in 32.3% cases and downgrade in 8.3% cases (39).

Another recent study, based on the comparison between different types of systematic biopsies, targeted biopsies and their combination with the final histopathologic diagnosis of radical prostatectomy, revealed a concordance in grade group of 49.4% for systematic biopsies, 51.2% for targeted biopsies, and 63.2% for both types of biopsies. For cases with grade group ≥ 2, the concordance was 41.2% for system-

atic biopsies, 48.3% for targeted biopsies, and 56.7% for both types of biopsies (41). As general remarks, the upgrade process is correlated with a poor outcome (40), the total number of cores and other previous biopsies were significant independent predictive factors for concordance in targeted biopsies (41), and the need of other potential factors to predict biopsy concordance is recognized (38).

CONCLUSIONS

Our results demonstrate an increase in the predictive accuracy of prostate biopsy, as a result of the application of prognostic grade group system, which ensure the decrease of overestimating tendency of the old scoring system, ultimately leading to a preliminary characterization of potential lesions in prostatectomy specimens and a more effective treatment stratification of patients.

MULTIMORBIDITY: HOUSEHOLD AND AREA-LEVEL SOCIAL DETERMINANTS

The study aimed to systematically review the existing literature on associations between household and area-level social determinants of health (SDoH) and multimorbidity prevalence or incidence in the general population. Methods Six databases (MedLine, EMBASE, PsychINFO, Web of Science, CINAHL Plus and Scopus) were searched. The search was limited to peer-reviewed studies conducted in high-income countries and published in English between 2010 and 2019. Authors included 41 studies spanning North America, Europe and Australasia. Household income and area-level deprivation were the most explored with fairly consistent findings. The odds of multimorbidity were up to 4.4 times higher for participants with the lowest level of income compared with the highest level. Those living in the most deprived areas had the highest prevalence or incidence of multimorbidity (pooled OR 1.42, 95% CI 1.41 to 1.42). Associations between deprivation and multimorbidity differed by age and multimorbidity type. Findings from the few studies investigating household tenure, household composition and area-level rurality were mixed and contradictory; homeownership and rurality were associated with increased and decreased multimorbidity, while living alone was found to be associated with a higher risk of multimorbidity and not associated. In conclusion, improving the understanding of broader social determinants of multimorbidity, particularly at the household level, could help inform strategies to tackle multimorbidity. (Ingram E, Ledden S, Beardon S, *et al.* Household and area-level social determinants of multimorbidity: a systematic review. *J Epidemiol Community Health* 2021;75: 232-241).

THYROGLOSSAL DUCT CYST - OLD AND NEW SURGICAL APPROACH (Abstract): The thyroglossal duct cyst (TDC) results from a failure in obliterating the embryogenic duct produced during thyroid migration and it represents the most common type of developmental cyst encountered in the neck region. **Material and methods:** In the First Surgical Clinic from "Sf. Spiridon" County Clinical Emergency Hospital Iasi, Iasi, between 1998 to 2021, 21 patients with thyroglossal duct cyst were diagnosed and treated. All medical records were reviewed. **Results:** The thyroglossal duct cysts are located as midline cysts of the neck in all cases. The mean age was 39.2 years (13-66 years). The treatment performed was a variant of Sistrunk's procedure in which the thyroglossal tract was excised to a variable extent, with central hyoidectomy. The size of the cyst ranged from 1.2 to 4 cm (mean 2.6 cm). Postoperative course was uneventful in all cases. No recurrence was recorded in this series. We describe a case, a 42 years old women, with asymptomatic mass in the anterior part of the neck found a 6 months before, when the patient was referred us with lithiasic obstructive jaundice (we performed ERCP + laparoscopic cholecystectomy). The treatment performed was a variant of Sistrunk's procedure in which the thyroglossal tract was excised by minimally invasive video-assisted approach, variation of Miccoli's technique. Postoperative course was uneventful. The follow-up 1 and 2 years no recorded recurrence and thyroid scintigraphy was normal. **Conclusions:** The standard surgical approach to TDC is Sistrunk's operation with low recurrence rates. Although the results and the operative time are the same as in traditional surgery, minimally invasive video-assisted approach has better cosmetic result and a less painful course. **Keywords**: THYROGLOSSAL DUCT CYST, MINIMALLY INVASIVE VIDEO-ASSISTED APPROACH, SISTRUNK'S OPERATION.

The thyroglossal duct cyst (TDC) is a developmental abnormality who results from a failure in obliterating the embryogenic duct during thyroid migration and it represents the most common type of cyst from neck region (1). The location of the cyst can be intralingual, suprahyoid, thyrohyoid or suprasternal region or even in hyoid bone (2). TDCs are diagnosed in children but there is also a small percentage of the adult population. A cyst is a mobile, painless mass in the anterior midline of the neck and most patients present inside the cyst ectopic thyroid tissue which in rare cases can cause the development of neoplasms. The mean rate of overall recur-

rence reported in literature is 11% and the Sistrunk procedure appears to be the better choice for the therapy of TGDCs to avoid recurrences (3).

MATERIAL AND METHODS

In the First Surgical Clinic from "Sf. Spiridon" County Clinical Emergency Hospital Iasi, between 1998 to 2021, twenty-one patients with TDCs were selected and all medical records were reviewed.

In twenty cases with TGDCs we performed traditional Sistrunk's surgery and in one case the thyroglossal cyst was excised by minimally invasive video-assisted approach. The inclusion criteria were diagnosis of a TGDC by physical examination and ultrasound scan. All patients provided informed consent after the advantages and disadvantages of each procedure.

The statistical data were compared with *SPSS for Windows 10* and a p-value of <0.05 was considered statistically significant.

RESULTS

There were 18 females (85.7%) and 3 males (14.3%) with mean age 39.2 years ± 12.5 years (13-66 years) with no significance differences between female and male patients. The mean age of onset of symptoms was 24± 2.5 years. The history of the disease varied from 1 month to 36 years. 20 patients with thyroglossal duct cysts are described as midline cysts of the neck and only in one case the cyst was located laterally.

The commonest reasons for seeking treatment were cystic neck mass which moved with protrusion of the tongue and could be transilluminated (17 cases), neck swelling (2 cases), neck infection (1 case) and dysphagia (1 case). The level of the cysts in the neck was as follows: 2 in the suprahyoid region, 12 in the prehyoid region, 6 at the level of the thyroid cartilage without any statistical significance related to age, sex or size (*t-student,* χ^2, p>0.05). One case was diagnosed with an external fistula with recurrence of 10 years after cyst removal. In three cases thyroid pathology (goiter) was associated.

In this series all patients were operated on, only one case initially was treated with antibiotics for infected thyroglossal cysts. The treatment performed was a variant of Sistrunk's procedure in which the thyroglossal tract was excised to a variable extent. We performed a 4-5 cm horizontal skin incision in the cervical region and created a flap that extended 1 cm above the hyoid bone, divided the median raphe of the strap muscles, dissected and cut the hyoid bone with careful dissection of the tract, extending to the tongue base.

The size of the cyst ranged from 15 to 60 mm (mean 29 mm ± 18.33 mm). The mean blood loss was 25 mL. (ranging from 10 to 57 mL) being statistically significant related to the size of the cyst (t student, p=0,008). Postoperative course was uneventful in all cases. The mean hospital stay was 4.8 ± 2.56 days. Although there were no significant differences in terms of cyst location and hospital stay length (χ^2, p>0.05). In this series no recurrence was recorded. The cysts were successfully removed in all cases, and the pathology results indicated that all of the cysts were TGDCs.

In one case the histopathologic diagnosis was a papillary carcinoma evolving from a TDC. Initial we didn't do anything because the clinical exam, ultrasound and scintigraphy of the thyroid was normal, but after ten years the patient developed a nodular goiter and we performed total thyroidectomy.

We describe a case in view in order to highlight of the new therapeutic option for the surgical management. 42-year-old women was admitted in emergency in the First Surgical Clinic, "Sf. Spiridon" County Clinical Emergency Hospital Iasi with lithiasic

obstructive jaundice for which it was performed endoscopic retrograde cholangiopancreatography (ERCP) with endoscopic sphincterotomy and extraction of gallstones of 1 cm and laparoscopic cholecystectomy with uneventful postoperative course. At the clinical examination of the patient we discovered an asymptomatic mass in the anterior part of the neck. Ultrasound scan revealed a cystic mass of 37 mm.

Fig. 1. Ultrasound scan - 37 mm thyroglossal cyst with a thick content.

After 6 months the patient had referred us and the clinical diagnosis discovered a cystic mass 3 cm, fibroelastic, which moved with protrusion of the tongue mobile and during swallowing. The cyst is located towards the front of the midline neck and could be transilluminated. Ultrasound scan revealed a slight increase in the size of the cyst to 37 mm with a thick content and thyroid gland was within normal limits (fig. 1). The thyroid scintigraphy was normal. CT scan was not performed.

The treatment performed was a variant of Sistrunk's procedure by minimally invasive video-assisted central neck approach, variation of Miccoli's technique. The patient was positioned on the operating table in dorsal decubitus, without neck hyperextension. A horizontal incision is made 2 cm above the suprasternal notch, in an existing skin fold, and created a working space by retraction with 2 divergent Farabeuf retractors (fig. 2). Under visual control the cyst was excised with clip application to the base of the thyroglossal tract and suturing in anatomical layers (fig. 3). The operation time was 45 minutes, blood loss was minimal and without drainage.

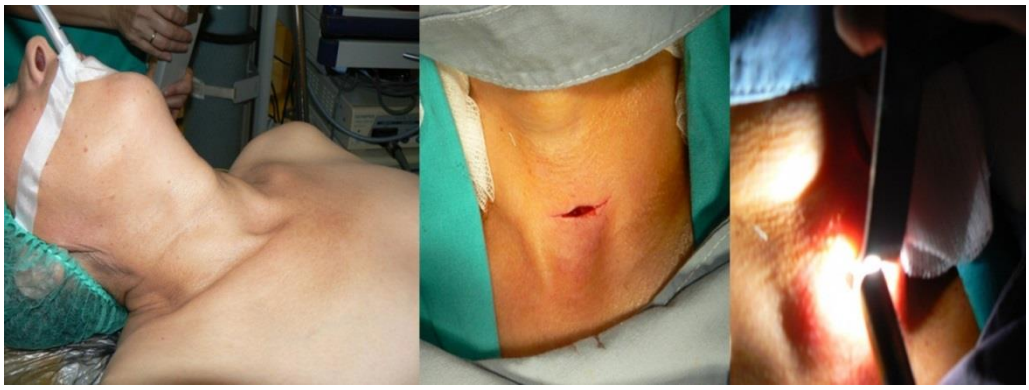

Fig. 2. The patient's position on the operating table in dorsal decubitus without neck hyperextension; a horizontal incision is made 2 cm above the suprasternal notch; created a working space by retraction with 2 divergent Farabeuf retractors.

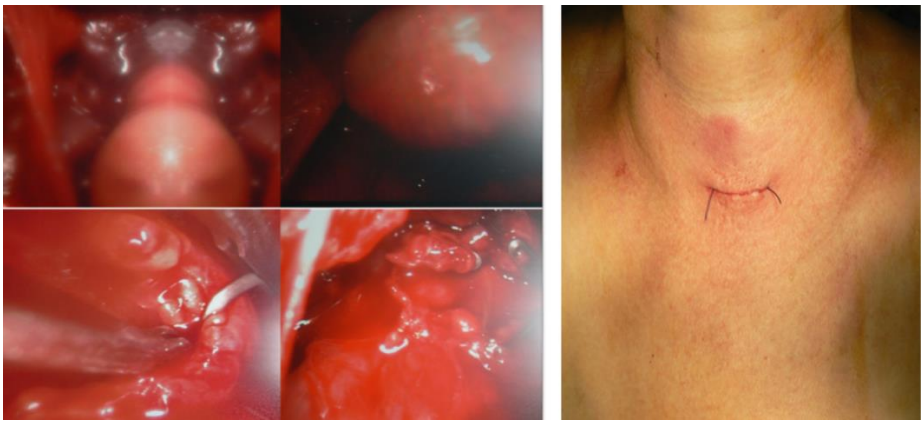

Fig. 3. Excision of the cyst under visual control with clip application to the base of the thyroglossal tract and final appearance after intradermal skin suture.

Postoperative course was uneventful and the patient was discharged after two days. The histopathologic exam revealed presence in cyst of ectopic thyroid tissue. The follow-up 1 and 2 years no recorded recurrence and thyroid scintigraphy was normal.

DISCUSSION

The failure of obliteration of thyroglossal duct in the 10th week of fetal life may result in the development of a cystic dilatation at any time in life. TDCs are localized towards the midline between the base of the tongue and the pyramidal lobe of the thyroid gland. Most of them are diagnosed in in the pediatric age group and few cases are diagnosed in adulthood (1).

The clinical diagnosis reveals a non-tender, mobile neck mass, which was painful at swallowing in the anterior midline of the neck, usually in close proximity to the hyoid bone and in rare cases the cysts are located laterally (1, 3).

Usual preoperative evaluation of thyroglossal duct cyst includes a cervical radiography, ultrasound scan, scintigraphy with 131I, thyroid function tests and for cases with malignancy and ectopic cysts, Computerized tomography has also been performed for selected cases.

The standard surgical approach to TDCs is Sistrunk's operation: removal of the mid-portion of the hyoid bone in continuity with the TDC and excision of a core of tissue between the hyoid bone and the foramen cecum. This procedure remains the gold standard for surgical management of TGDCs.

The first video-assisted neck surgery, namely a subtotal parathyroidectomy, was performed by Michel Gagner in 1996 and minimally invasive video-assisted central neck approach was first described by Miccoli in 1998 for thyroid pathology. The first thyroidectomy by minimally invasive video-assisted approach (MIVAT) in Romania was performed in 2009 at the First Surgical Clinic, "Sf. Spiridon" Hospital by Bradea and Târcoveanu (4).

About minimally invasive video-assisted approach in thyroglossal duct cyst there are few references in the literature. Huang Z *et al.* describe no recurrences after 15 endoscopic thyroglossal duct cystectomy (5). Woo SH *et al.* considering the

embryological development of TGDCs, can open a new access route to these cysts. Performed endoscope-assisted transoral removal in 13 cases with mean operation time 67.33 ± 17.26 minutes, no scars and also no recurrences (6). Han P *et al.* performed surgical resection using a submaxillary vestibular approach in 16 cases with TDCs with good results: no postoperative complications and no conversions of the operation (7). Byeon HK *et al.* describe first robot-assisted approach for synchronous occurrence of thyroglossal duct carcinoma and thyroid carcinoma (8).

When a histopathological examination reveals a malignancy, the thyroid gland must be studied radiologically and scintigraphically. Sistrunk's procedure would suffice if the thyroid gland was found to be normal (9). The occurrence of carcinoma of the thyroglossal duct is reported to be less than 1%. The clinical diagnosis of thyroglossal duct cyst is completed by ultrasound (US) scan and fine-needle aspiration cytology (FNAC) in order to plan the correct surgery for a possible carcinoma. In these cases, total thyroidectomy should be associated with Sistrunk procedure (SP) to permit the correct treatment and follow-up (10). For patients with thyroglossal duct cyst carcinoma and a normal thyroid gland, a mutational marker BRAFV600E positivity seems to be predictive of locally advanced disease mandating radioactive iodine ablation (RIA) therapy, therefore total thyroidectomy, in addition to Sistrunk's procedure (11).

CONCLUSIONS

The standard surgical approach to TDC is Sistrunk's operation with low recurrence rates. Although the results and the operative time are the same as in traditional surgery, minimally invasive video-assisted approach is a safe and effective procedure with better cosmetic outcomes and a less painful course.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

CARDIAC MYXOMA AS CYTOKINE PRODUCING TUMOUR: A REVIEW

Cardiac myxoma is the most common primary cardiac tumor. Many cytokines participate in the pathophysiology and growth of cardiac myxoma. Inflammatory cytokines, including interleukin-1, interleukin-4, interleukin-6, interleukin-8, interleukin-12, tissue necrosing factor-α, and interferon-γ, contribute to the development of inflammation and inflammation-related symptoms and further affect tumor growth. Growth factors, including vascular endothelial growth factor, basic fibroblast growth factor, insulin-like growth factor 1, and epidermal growth factor, contribute to angiogenesis and tumor growth and interfere with the inflammatory response. This review summarizes the current knowledge of cardiac myxomas as cytokine-producing tumors (Ajiro Y. Cardiac myxoma as cytokine producing tumor: A review. *Interv Cardiol* 2021; 13(S3): 58-63).

DIAGNOSIS OF MYOCARDIAL INFARCTION AT AUTOPSY: AECVP REAPPRAISAL IN THE LIGHT OF THE CURRENT CLINICAL CLASSIFICATION

Ischemic heart disease is one of the leading causes of morbidity and death worldwide. Consequently, myocardial infarctions are often encountered in clinical and forensic autopsies, and diagnosis can be challenging, especially in the absence of an acute coronary occlusion. Precise histopathological identification and timing of myocardial infarction in humans often remains uncertain while it can be of crucial importance, especially in a forensic setting when third person involvement or medical responsibilities are in question. A proper post-mortem diagnosis requires not only up-to-date knowledge of the ischemic coronary and myocardial pathology, but also a correct interpretation of such findings in relation to the clinical scenario of the deceased. For these reasons, it is important for pathologists to be familiar with the different clinically defined types of myocardial infarction and to discriminate myocardial infarction from other forms of myocardial injury. This article reviews present knowledge and postmortem diagnostic methods, including post-mortem imaging, to reveal the different types of myocardial injury and the clinical pathological correlations with currently defined types of myocardial infarction (Michaud K, Basso C, d'Amati G, *et al.* Diagnosis of myocardial infarction at autopsy: AECVP reappraisal in the light of the current clinical classification. *Virchows Archiv* 2020; 476: 179-194).

COMPARATIVE STUDY ON CLASSIC *VS*. DIGITAL IMPRESSION IN FIXED PROSTHETICS (Abstract): Intraoral digital impression is a revolutionary breakthrough and an important step forward in dentistry due to its accuracy in achieving high-precision prosthetic work on natural teeth or dental implants. The **aim** of this study is to analyze the established differences between the digital impression and the classic impression in relation to the specific features of the clinical case. **Material and methods:** The study included 58 patients diagnosed with partially reduced edentulousness or with extensive destruction of the dental units who received fixed therapy anchored in a non-metallic registry of prosthetic restorations represented by ceramic crowns on zirconium support. **Results:** Optical impression in conventional prosthetics plays a very important role as it is the first step in the complete digital line of prosthetic construction. The accuracy and precision of the impressions are key points in the marginal fit of the prosthetic work and therefore in the success of the prosthetic treatment. **Conclusions:** Dental digital impression is a non-invasive, simple, practical, accurate and patient-friendly procedure that eliminates many of the inconveniences of conventional impressions. **Keywords:** DIGITAL IMPRESSION, CLASSIC IMPRESSION, FIXED RESTAURATION.

Impression in dentistry is an essential step in the realization of various prosthetic dental works (in fixed prosthetics - dental crowns, crowns on implants, dental bridges or in mobile and removable ones), orthodontic, or surgical impression materials have been developed and improved over time, from the classic plaster, Stents, to irreversible hydrocolloids and synthetic elastomers. Despite the impeccable quality of modern impression materials, there remain drawbacks during the impression stage that can ultimately jeopardize the quality of prosthetic restorations and their fit on the patient's prosthetic field. Given the astonishing progress of technology, this is inevitably also felt in the field of dentistry (1, 2).

Intraoral digital impression is a revolutionary breakthrough and an important step forward in dentistry due to its accuracy in achieving high-precision prosthetic work on natural teeth or dental implants. Optical impression in conventional prosthodontics plays a very important role as it is the first step in the complete digital line of prosthet-

ic construction. The accuracy and precision of the impressions are key points in the marginal adaptation of the prosthetic work and therefore in the success of the prosthetic treatment (3).

Some of the **benefits** of digital impressions are represented by:

1. Elimination of possible causes of errors due to traditional classic impressions, such as: Incorrect choice of impression tray, either of the wrong size or made of plastic material, which can easily deform; the most suitable tray for the classical procedure is the individual resin impression tray, adapted to the unique situation in each patient's mouth; since it does not require an impression tray, there is no longer the inconvenience of the impression material not adhering to the tray and deforming on removal; if the impression material is stored improperly, its setting time changes, so additional deformation may occur; it is sometimes necessary to redo the impression if areas of missing substance or incorrect registration are observed, which means wasted material and extra time spent in the office; if defects appear in the working model, the impression must be returned, but its fidelity will no longer be as it was originally; in the case of digital impressions, the information is not lost, as it is stored in the computer, so the fidelity of the impression will be fully preserved (4, 5).

2. Increased patient acceptability: The small size of the intra-oral scanner eliminates the inconvenience of holding the bulky, material-laden impression tray in the mouth, which makes many patients feel sick; at the same time, a number of patients may experience allergic reactions to impression materials, which do not occur with digital technology; the risk of swallowing impression material if handled incorrectly is eliminated. The method is advantageous for patients who have problems tolerating conventional impressions for various reasons: microstomia, exaggerated gag reflex, torus (maxillary or mandibular), other retentive areas in the prosthetic field that may interfere with the removal of the impression after the impression material has been taken (1, 6).

3. The dental digital impression is also more comfortable and safer for the clinician, as it does not need to be sanitized like a traditional impression, so contact with patient fluids and tissue debris is reduced and the risk of contamination with various pathogens is minimized; ♦ high accuracy leading to perfect adaptation of work; automatic and immediate color registration; ♦ immediate control and verification of dental preparations.

4. Reduced distortion of impression material;

5. Accuracy - any microdetail of the prosthetic field (teeth, implants, gums, fillings, work) are recorded at micron level with maximum accuracy

6. A wide range of dental indications (crowns, veneers, inlays, root canal devices, implants)

7. 3D preview of the preparation;

8. Reduced costs of impression materials, individual impression trays, plaster for model making; ♦ no need to stock and purchase impression trays and impression materials; ♦ the need for long-term storage of models is eliminated.

9. No risk of microbial contamination for the dental laboratory (no physical contact with the impression);

10. The information (impression) can be transmitted electronically immediately to the laboratory (by e-mail);

11. Clinical data related to the preparation, neighboring teeth, antagonists, intermaxillary reports, are kept in files, without

any changes, for a virtually unlimited period of time.

12. Quality treatment - an accurate impression will always generate an accurate work.

Dental digital impression is therefore a non-invasive, simple, practical, accurate, patient-friendly procedure that eliminates many of the inconveniences of traditional impressions, but for an exceptional final result, the doctor's contribution is important. Even if in the future research will continue and dentistry will rely on modern instruments, the human factor is indispensable and cannot be substituted (7, 8).

MATERIAL AND METHODS

The aim of this study is to analyze the established differences between the digital impression and the classic impression in relation to the specific features of the clinical case.

The study included 58 patients diagnosed with partially reduced edentulousness or with extensive destruction of the dental units who received fixed therapy anchored in a non-metallic registry of prosthetic restorations represented by ceramic crowns on zirconium support.

A series of parameters were analyzed: the time allocated to the registration of the impression, a particularly important stage in the clinical-technological algorithm of fixed prosthodontics, the clinical evaluation of the restorations in the frame in the case of optical impression prosthodontics and classical impression prosthodontics, as well as the patient evaluations using a visual analogue scale.

RESULTS

The results of the study are presented in first table. The time spent on the digital impression is much shorter than the classic impression, the digital technique being more convenient for both clinicians and patients.

TABLE I

The results of the study

No.	Procedure	Time spent (classical technique)	Time spent (digital technique)
1	Impression	11:14 ± 01:33	07:10 ± 02:10
2	Dentist`s assessment	47.01 ± 20.10	23.39 ± 17.03
3	Patient`s assessment	43.79 ± 26.10	6.20 ± 5.32

DISCUSSION

However, there are also **obstacles and difficulties** encountered in optical impressions. These include the following: ♦ some systems require the teeth to be powdered with a special spray prior to scanning and the uneven layer of powder can lead to inaccuracy; ♦ complexity - the equipment is sophisticated and requires instruction and training to master the technique; ♦ the time needed for the actual scanning maneuver is longer compared to traditional impressions; ♦ cost of purchasing equipment (scanner, software and/or milling machine - for closed systems); ♦ the size of scanners (e.g., iTero) can be problematic when trying to impression 2nd or 3rd molars; ♦ in the case of subgingival preparations, it is difficult to impression the preparation margins.

Even if the digital impression technique proves its superiority in many aspects, including ease of execution, it has a weakness, which can only be overcome with the help of the clinician's experience and pro-

fessionalism. We are talking about the registration of subgingival preparations and the gingival sulcus, which can compromise the marginal fit of the prosthetic piece, making treatment a failure. The scanner records the same images that the clinician can perceive with the naked eye, so for the correct reproduction of the gingival boundary it is mandatory to ensure visibility, by correctly performing the gingival eviction and by the best possible isolation of the prosthetic field (the dam being the most suitable) (9, 10).

Digital impression is performed by intraoral scanning, a method using the triangulation technique. Intraoral scanners (IOS) are devices used to take digital impressions and collect information about the shape and size of dental arches by emitting a light beam. They project a light grid (structured light or laser) onto the tooth surface and capture, through high-resolution cameras, the distortion that such a beam undergoes when it hits those structures (Fig. 1).

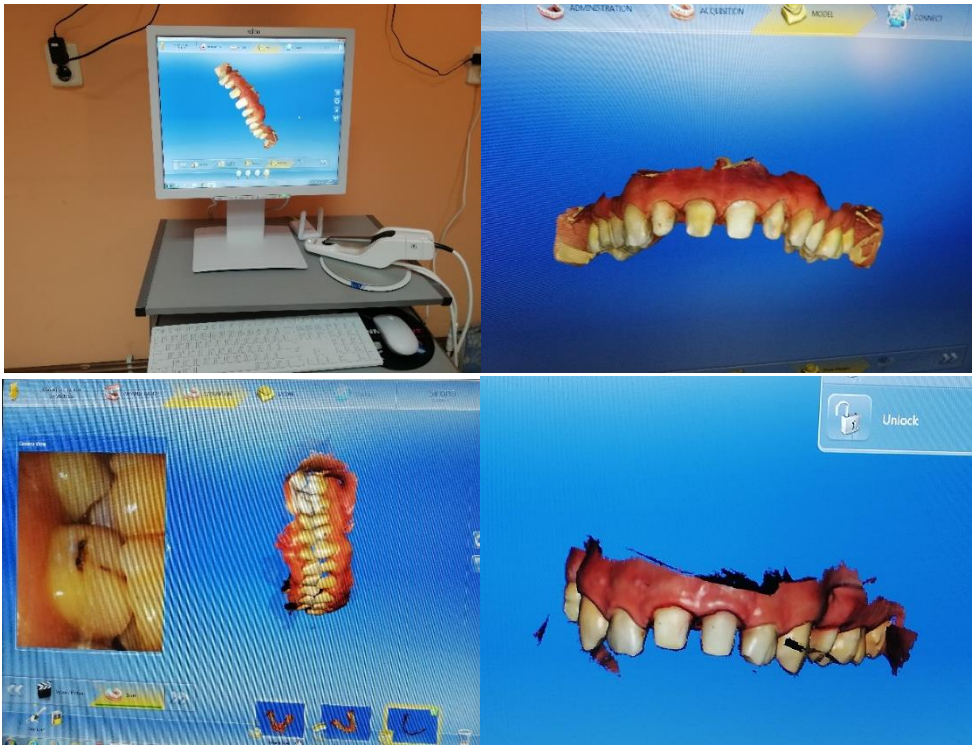

Fig. 1. Practical aspects of digital impression

The intraoral scanning protocol involves the following clinical steps: ♦ application of a retraction wire to expose the contour of the polished bridge and subgingival sills; ♦ directing the scanner to capture the image in multiple directions, specific to each type of scanner, according to the manufacturer's instructions, in order to obtain a digital impression of maximum precision (7, 11); ♦ scanning antagonists following the same principle.

Scanning of the prepared tooth or pros-

thetic field can be done by two procedures: ♦ intraoral scanning, direct and fast, the data can be sent immediately by e-mail in STL format to the CAM laboratory where the prosthetic work is made; ♦ extraoral scanning, indirect, applied on the conventional final impression or on the cast model after the impression sent to the laboratory; although it is a more time-consuming procedure and the impression can be a potential source of error, it is preferred by the doctor because of the cost of the investment for the intraoral scanner (12, 13).

Intraoral image capture is performed by shooting with multiple frames of approximately 3 teeth in the case of iTero (Align Technology), Trios Color (3 Shape) or CS 3500 (Carestream Dental LLC) scanners, respectively video shooting as found in True Definition Scanner (3M ESPE), CEREC Omnicam (Sirona), Apollo DI (Sirona), PlanScan (Planmeca) equipment (Iliescu). The registration of larger areas is done by superimposed images that are assembled by a computer program, generating a virtual 3D model in which the areas not directly imaged are completed by extrapolation. Inaccuracy of the fit of the prosthetic restoration to the tooth is due to two factors (14, 15, 16): ♦ main factors: accuracy of tooth preparation and the appropriate 3D virtual design on the computer; ♦ additional dental factors: location of the coronal prosthetic preparation margins, location of the crown equator, location of retentions; ♦ digital additional factors: quality of digitized data acquisition, quality of data processing, efficiency of noise removal filters induced by measuring systems (14, 15).

To date (2017), the scientific literature considers the accuracy of optical impressions to be clinically satisfactory and similar to that of conventional impressions in single-tooth restorations and fixed partial dentures up to 4-5 elements. However, optical impressions do not appear to have the same accuracy as conventional impressions for larger restorations (fixed partial dentures with more than 5 elements or full bridges on natural teeth or implants). However, accuracy and precision are not the only elements that can differentiate commercially available devices today. A whole series of elements (need for powder application, scanning speed, tip size, color detection capability) differentiate scanners in terms of their clinical use (17, 18, 19).

Scanners are very useful devices and are indicated in various areas of dentistry (both for diagnosis and for the fabrication of restorations): prosthodontics, implantology, orthodontics.

In 2020, Kanchan Aswani *et al*., analyzed 507 PubMed indexed articles (2018-2019). Following the application of exclusion criteria (articles published in a language other than English, review articles, articles evaluating the marginal fit of different restorations, etc.) 412 articles were eliminated. Only 95 articles that met the inclusion conditions (articles published in English, clinical or laboratory studies, etc.) were considered. Compared to conventional impressions, optical impressions eliminate several clinical and laboratory steps in the fabrication of prosthetic parts.

Thus, the clinical steps eliminated are: ♦ choice of impression tray; ♦ preparation of the material; ♦ the actual impression; ♦ decontamination of the impression; ♦ referral to the dental laboratory. The laboratory steps eliminated are: ♦ casting the model; ♦ sectioning; ♦ establishing intermaxillary ratios; ♦ scanning the models individually and in occlusion.

In 2014 Yuzbasioglu *et al.* conducted a study on 24 patients (12 males, 12 females).

The study findings were: ♦ the digital impression technique was more efficient than the conventional technique (the working time for the conventional impression was longer than that for the digital technique); ♦ compared to the conventional technique, the digital technique was more efficient; it was accepted and preferred by patients; ♦ the comfort of the digital technique was higher than that of the conventional method.

CONCLUSIONS

Due to its accuracy, short duration, patient comfort and last but not least due to the reduction of material consumption, intraoral scanning has gained increasing popularity and is expected to gradually replace the traditional impression. With the help of a high-performance intraoral scanner, it is now possible to quickly send an accurate digital impression electronically to the dental laboratory directly in the dental practice by the dentist. The introduction of digital technology as a standard procedure for the fabrication of prosthetic restorations is unfortunately still hampered by the need to train highly qualified staff and by the cost price reduction, which is still far too high compared to conventional procedures. Optical impression in conventional prosthetics plays a very important role as it is the first step in the complete digital line of prosthetic construction. The accuracy and precision of the impressions are key points in the marginal fit of the prosthetic work and therefore in the success of the prosthetic treatment.

Dental digital impression is a non-invasive, simple, practical, accurate and patient-friendly procedure that eliminates many of the inconveniences of conventional impressions. Digital impression was originally used in prosthodontics as part of CAD/CAM technology to shorten work steps and achieve a fully digital workflow. In dentistry, digitized technology is slowly but surely taking the place of traditional procedures. From diagnosis to the final tooth, any dental procedure performed digitally is more accurate, safer, and better tolerated by the body.

CONFLICT OF INTEREST AND FUNDING

Authors declare that there is no conflict of interest, and they received no funding for this study.

NEWS

HIGH-DOSE OF ASCHORBIC ACID CAN IMPROVE SYMPTOMATOLOGY OF CORONAVIRUS INFECTION

Following the outbreak of the pandemic, whose promoters are SARS CoV-2 and MERS CoV, studies show that an attempt was made to quickly find a solution that involved immunizing the population, making a vaccine, or finding the right treatment to increase survival by administering antivirals, corticosteroids or of other substances that stimulate immunity and decrease the oxidative stress potentiated by the infection. According to studies, the oxidative way in which viruses cause damage to organs, finding that at the base is an oxidation-reduction reaction that causes severe inflammatory reactions, increasing the number of reactive oxygen species degenerating the antioxidant system of the airways. Related studies have shown the positive effect of high doses of vitamin C by significantly lowering inflammatory markers by its reducing effect that reduces reactive oxygen species that cause such serious damage. (Hoang BX, Shaw G, Fang W, Han B, Possible application of high-dose vitamin C in the prevention and therapy of coronavirus infection. *J Glob Antimicrob Resist* 2020; 23: 256-62).

CURRENT APPROACHES IN FIXED PROSTHESES ON ZIRCONIUM SUPPORT

CURRENT APPROACHES IN FIXED PROSTHESES ON ZIRCONIUM SUPPORT (Abstract): Zirconium oxide is a superior material in terms of biocompatibility with adjacent tissues, color similar to natural teeth, resistance to daily masticatory stress and abrasion, chemical stability in high-quality restorations and last but not least translucency. The aim of the study is to individualize the therapeutic aspects of non-metallic zirconia restorations anchored in the register of contemporary non-metallic dentistry in accordance with the particularities of clinical cases and the requirements of the technological line addressed. A total of 34 zirconia-supported ceramic prosthetic restorations were made for the morpho- functional rehabilitation of various edentulous areas of the maxillary and mandibular arches. As far as the technological specifics of these types of restorations are concerned, Exocad software and MEDIT 300 scanner and Cerec CAD-CAM system were used. In dentistry, digitized technology is slowly but surely taking the place of traditional procedures. From diagnosis to the final tooth, any dental procedure performed digitally is more accurate, safer, and better tolerated by the body. **Keywords:** ZIRCONIUM, CAD/CAM, SOFTWARE, AESTHETICS.

In terms of technological developments and biomaterials required in complex oral rehabilitations, for a long time acrylic resins, metals, composites and ceramics have been chosen in combination with noble (gold or silver-palladium based), non-noble (Cr-Ni, Cr-Co, Cr-Ni-Be based), titanium alloy infrastructures. Moreover, modern all-ceramic systems (InCeram, Empress, Vita), zirconium oxide systems, all-polymer systems, and therapeutic solutions based on these materials are used in contemporary prosthetics to improve the aesthetic result (1, 2, 3).

The social impact on the patient makes the dentist's choice of biomaterial a decision based on relevant arguments, considering the particularities of the clinical case in question and the patient's aesthetic requirements (4, 5, 6).

Currently, all-ceramic restorations are the most commonly used therapeutic alternative compared to ceramic work on metal infrastructure. Although the lack of either alloy or zirconium infrastructure may cause a decrease in mechanical strength over

time, biocompatibility achieves superior aesthetic ratings, thus becoming a solution that captures the attention of patients who place a primary emphasis on aesthetics (7, 8, 9).

Another material that revolutionized dentistry and was discovered in 1789 by the German chemist Martin Heinrich Klaproth is zirconium oxide, a white-ivory-colored ceramic material noted for its variety and remarkable properties such as high flexural strength and hardness. Zirconium oxide is a superior material in terms of biocompatibility with adjacent tissues, color similar to natural teeth, resistance to daily masticatory stress and abrasion, chemical stability in high-quality restorations and last but not least translucency (10, 11, 12).

These advantages make it the material of choice in contemporary dentistry (for crowns, bridges, implants), but also in the medical field in general for the production of bone prostheses, hearing aids, etc.

There are two types of zirconium oxide restorations:

- Restorations made entirely of zirconium which have a very high resistance to mastication forces and can therefore also be used for prosthetic work in the lateral area(13, 14).
- Restorations with a ceramic layer on zirconium substructure, which can be indicated especially in the frontal areas of dental arches.

The realization of a ceramic prosthetic work on zirconium infrastructure requires the accurate completion of an algorithm that includes clinical and technological steps that follow a certain sequence.

AIM

The aim of the study is to individualize the therapeutic aspects of non-metallic zirconia restorations anchored in the register of contemporary non-metallic dentistry in accordance with the particularities of clinical cases and the requirements of the technological line addressed.

MATERIAL AND METHODS

A total of 34 zirconia-supported ceramic prosthetic restorations were made for the morpho functional rehabilitation of various edentulous areas of the maxillary and mandibular arches. As far as the technological specifics of these types of restorations are concerned, Exocad software and MEDIT 300 scanner and Cerec CAD-CAM system were used.

The clinical and paraclinical examination of the patient is the first stage of the algorithm, in which the diagnosis will be clarified, and the treatment plan will be established in accordance with the wishes of the patient, who must participate in the establishment of this therapeutic strategy, giving their consent in the case of treatment objectives. The preparation of the prosthetic field, the preparation of the organic substructures with the least possible sacrifice of amelo-dental tissue is the next extremely important stage. Special attention must be paid to the space required for the future prosthetic construction, in relation to neighboring and antagonist teeth, so as to ensure optimal retention and the possibility of insertion. The preparation of the socket is equally important as it directly conditions the marginal dento-prosthetic closure. After ticking off the specific preparations for the application of ceramic prostheses on the zirconium infrastructure, the dentist

carries out the registration of the main and peripheral elements of the prosthetic field.

RESULTS AND DISCUSSION

Prosthetic restorations made of zirconia-supported ceramics have brought together both single restorations and small-width dental bridges in keeping with the partially reduced edentulousness they have rehabilitated.

Thus, a percentage of 48.7% was recorded for single crowns that rehabilitated dental units affected by coronal lesions with varying degrees of destruction, while rehabilitation using dental bridges covered a percentage of 51.3% that ensured morphological restoration of dental arches in accordance with the parameters of the potential prosthetic spaces (fig. 1).

As regards the location of prosthetic restorations of single crowns were located in the maxilla, 57.9% in the posterior region and 85.4% in the anterior region, which was recognized by the degree of aesthetic requirements of the restorations. As regards the prevalence of prosthetic restorations made of zirconia-supported ceramic, 14.6% of the restorations were located in the anterior mandibular area and 42.1% in the posterior area, which is associated with the degree of aesthetic restoration in conjunction with the degree of visibility during the tooth movement. As regards the topography of the zirconia-supported ceramic bridges, they were found in the posterior area in a percentage of 64% for the maxilla and 36% for the mandible, while the anterior locations were in a proportion of 66.7% for the maxilla and 33.3% for the mandible. The choice of these types of restorations was correlated with the masticatory forces with the potential prosthetic spaces with the other types of restorations, an important role being played by the static occlusion and the mandibular dynamic trajectories, as well as the type of smile for each individual patient. (fig. 2).

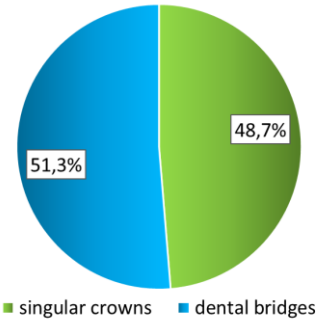

Fig. 1. Esthetic ceramic restoration on zirconia framework

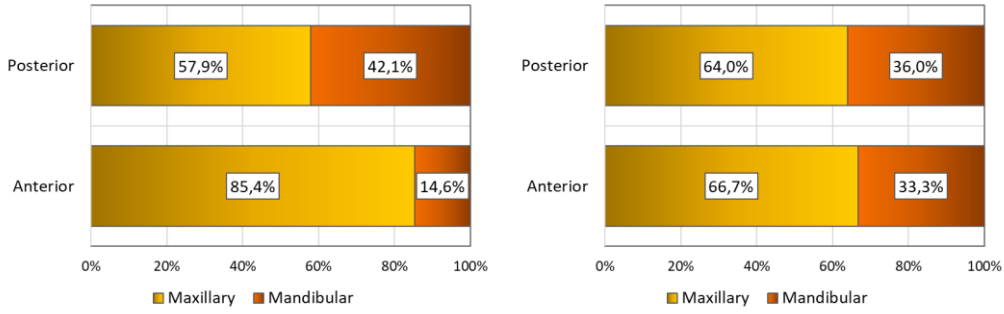

Fig. 2. Topography of single zirconia-supported ceramic crowns and bridges

Grafted on the addressed problem we selected some representative aspects. Restorative treatment begins with the preparation of the organic substructures by the dentist, according to the type of restoration, to create sufficient space for both components for optimal insertion and adaptation. From the clinical-technological algorithm we have selected the steps listed in the digital register with the identification of the working features.

The complex digital workflow uses Exocad software, DentalDB 2.2 Valletta and starts with the creation of the patient record in the Job definition window.

Scanning working models and occlusion: The Exocad software and the MEDIT 300 scanner are used to scan the entire complex. After selecting the simulator and the type of preparation, both the maxillary model, followed by the prepared prosthetic abutment and the mandibular model, together with the prepared abutments positioned according to the computer's instructions on the special holder (fig. 3) are inserted and fixed on the existing table inside the scanner. Finally, the models are scanned in occlusion, resulting in virtual models with the abutments positioned appropriately in the dental arches.

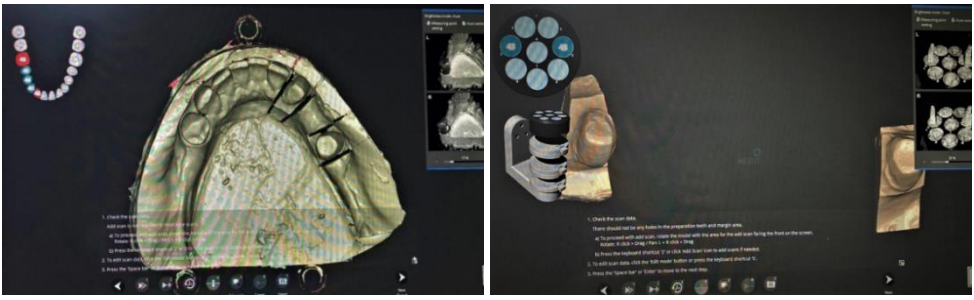

Fig. 3. Virtual representation of the lower model with movable abutments

Detection of the collars of each prepared substrate: In this case, the tracing of the collars was done automatically by making a few modifications to each abutment to obtain a more uniform and linear collar. **Determination of the unique insertion direction and thickness of the zirconia infrastructure:** For a perfect fit of the restoration, it is necessary to establish a single insertion axis for both the lower bridge and the individual upper crown, without certain differences in the proximal and occlusal faces. In the same step we select the space required for the luting cement of about 0.05 mm and the thickness of the zirconia infrastructure which is 0.6 mm in general (fig. 4).

Following these steps, the actual design of the zirconia caps and intermediate is carried out with the help of the software, which renders a general shape of a tooth gallery, according to previously established parameters.

Modifications are made to this shape using add, smooth, remove and also gingival adaptation of the bridge body. Once the optimal shape of the zirconia support has been established, the connectors are applied to connect the caps and the bridge body to each other.

A final step after completion of the zirconia infrastructure design is to save the design and import the file into the CAM software, where it will be placed on the zirconia disc belonging to CeraDirect, Super High Translucent Multilayer and programmed for milling .

Fig. 4. Establishing the insertion axis

Milling of the zirconium support: The disc is inserted and clamped in the 51D Roland enclosure, which mills the zirconia substructure in 5 axes using three types of milling cutters of 0.6 mm, 1 mm and 2 mm (figs. 5 and 6). After completion of the whole process, the milling machine is vacuumed, and the disc is removed and cleaned of impurities with an air jet.

Then the connectors supporting the caps are sectioned using special diamond cutters and the infrastructure is adapted to the level of the prepared organic substructure

Fig. 5. Fixing the zirconium disc

Fig. 6. Milling of zirconium infrastructure

Sintering: This stage aims to increase the strength and translucency of the previously adapted infrastructure. The prosthetic restorations, i.e., zirconium caps, are placed in ceramic vessels and then in the Nabertherm LHT 01/17D sintering oven .

They are subjected to a special sintering regime, which is usually specified by the zirconium disc manufacturer, rising to temperatures of 1,450°C over 6-18 hours.

Following the sintering process, the zirconium caps will have a different, undersized and colored appearance from the original appearance when removed from the disc. At this level a first sample of the infrastructure can be made in the dental surgery.

Application of ceramic masses: The layering technique is used, and the application of ceramic bodies is done with special brushes. A layer of Ivo color glaze is brushed onto the surface of the zirconium framework prepared for layering and powdered with a ceramic or silicate powder on

the lateral and occlusal sides to achieve better retention.

The caps are then placed on a refractory support and placed in the firing furnace at temperatures above 800°C for 14 min.

The ceramic layers shall be applied by the technique mentioned as follows:

- Application of IPS e. max Ceram dentin layer, D2 shade, with the help of a brush, in a thicker layer, achieving an oversized morphology. Place the work in the burning oven at 745°C for 15-20 min. After removal from the oven, wait for cooling and if necessary, the work can be processed.

After processing, the restoration is prepared for the glazing stage by removing impurities with the steamer and drying the work with an air jet.

- Application of the final glaze layer consists of brushing a liquid of viscous consistency over the entire surface of the lower dental bridge and the individual upper crown. Firing in the special furnace is carried out at a temperature of 745°C for 13-15 min. This final layer facilitates the highlighting of the chosen shade in agreement with antagonist and adjacent teeth and gives a glossy tint in order to achieve a superior aesthetic.

In order to create micro-retentions that will facilitate the definitive cementation in the patient's oral cavity, after the proper application of the ceramic masses, the internal faces of the ceramic crowns are sandblasted on zirconium infrastructure, using a corundum jet conveyed by compressed air.

The relevant aspects selected from the clinical-technological algorithm of the clinical case highlight the importance of choosing an optimal solution in accordance with the therapeutic principles, the clinico-biological indications of the prosthetic field to be restored and the patient's wishes at the aesthetic-functional level.

CONCLUSIONS

CAD/CAM systems are nowadays widely used in dentistry for making dentures. The introduction of these systems in dentistry has made it possible to meet the expectations of patients, who, with the help of chair-side systems, can benefit from high quality and precise prosthetic restorations in a single treatment session.

CAD/CAM systems have significantly revolutionized conventional techniques and protocols for prosthetic work, economic efficiency combined with the high quality of restorations has made this technology a subject of interest for doctors and technicians as well as for patients, who benefit from painless treatment and visible results in the shortest possible time.

In dentistry, digitized technology is slowly but surely taking the place of traditional procedures. From diagnosis to the final tooth, any dental procedure performed digitally is more accurate, safer, and better tolerated by the body.

EFFICACY OF SUBCUTANEOUS CLOSED SUCTION DRAIN IN REDUCTION OF POSTOPERATIVE SURGICAL SITE INFECTION

Surgical site infections (SSIs) are the infections of wound after an invasive operative approach. It remains to be a major morbidity for patients undergoing surgeries although there have been tremendous improvements in the surgical techniques. Different interventions to suppress the selective serotonin reuptake inhibitors have been proposed. Many of them have been routinely used by surgeons like minimizing shaving, hand washing, and preoperative antibiotics and these are well accepted. Drains are used in major abdominal surgeries, hernia repairs, breast surgeries reducing collections in closed areas. Hematoma, serous fluid and dead space in surgical incision wounds raise the risk of infection as they serve as the platform for microbial growth. Studies have proved that the usage of subcutaneous drains has lowered the chances of infection. According to this study the comorbid patients, emergency cases and colorectal surgeries had a higher incidence of developing SSI. The most common organism isolated was E. coli followed by S. aureus . The assessment of these variables therefore helps in providing a prophylactic treatment to reduce the mortality in the high-risk patients. (Harish R., Kazi F. N., & Sharma J. (2021). Efficacy of Subcutaneous Closed Suction Drain in Reduction of Postoperative Surgical Site Infection. *Surgery journal (New York, N.Y.)*, *7*(4), e275–e280.)

KEY ISSUES OF THE CHEMICAL PROPERTIES OF DRINKING WATER IN TIMIS COUNTY, ROMANIA

Cristina Petrescu[1,2*]
1. "Victor Babes" University of Medicine and Pharmacy Timisoara, Romania
2. Public Health Direction Timis, Romania

KEY ISSUES OF THE CHEMICAL PROPERTIES OF DRINKING WATER IN TIMIS COUNTY, ROMANIA (Abstract): The **aim** of the performed study was to identify the key issues with the chemical properties of the drinking water in Timis County, Romania. **Material and methods:** The observational case-study was conducted for two years (2016-2017) on a sample of 1,086 water sources (2,159 water tests) in Timis County. **Results:** The majority of the water chemical parameters fell under the Maximum Admitted Concentrations (MAC). Main key issues identified were excessive concentrations of manganese in Timisoara (mean-208 µg/L), of iron in Timis County (rural) (mean-239 µg/L) and of ammonia in Timis County (urban: Lugoj) (mean-0.96 mg/L) public wells. Manganese mean concentrations surpassed MAC (50 µg/L) in non-chlorinated water, for companies, individual and public wells, in both areas Timisoara and Timis County. Iron mean concentrations surpassed MAC (200 µg/L) in public wells in Timis County and Timisoara, in non-chlorinated water. Ammonia means concentrations exceeded MAC (0.5 mg/L) in chlorinated water, in Timis County, for companies and public sources, and in Timis County (rural) in public wells. In Timisoara from 444 water tests in public wells, only 269 were harvested for manganese, 274 for iron**. Conclusions:** excessive concentrations of manganese, iron and ammonia are the key issues with the chemical properties of drinking water in Timis County. **Keywords:** WATER CHEMICAL PARAMETERS, IRON, MANGANESE, AMMONIA, OBSERVATIONAL CASE-STUDY.

Timisoara (the capital of Timis County) and Timis county have a good representation of confined (wells with a depth over 80 meters) and surface water. Pumps are used to extract and conduct ground water to the surface and central water systems are used to treat and deliver surface water to consumers. Research studies indicated high values of nitrates, iron, and manganese in the neighbor areas with reduced drinking water quality (1, 2) and with pathology occurrence. There is a gap of knowledge in the area about the concentration of certain chemical elements in the water offered and consumed by the population. The aim of the performed study was to identify the key issues with the chemical composition of drinking water in Timis County and Timisoara.

MATERIAL AND METHODS

Material of study consisted of a sample of 1,086 drinking water sources (2,159 water tests) disinfected with chorine and non-disinfected, used by the general population in Timis County and Timisoara,

during two years of study (2016 and 2017) (fig. 1).

Monitoring and audit control was done by the Public Health Direction Timis (PHDT), especially for non-chlorinated water (927 sources).

For chlorinated water (159 sources) having as source surface waters (Bega and Timis rivers) the water control done by PHDT followed after a daily monitoring performed by the treating water plants in their own laboratories.

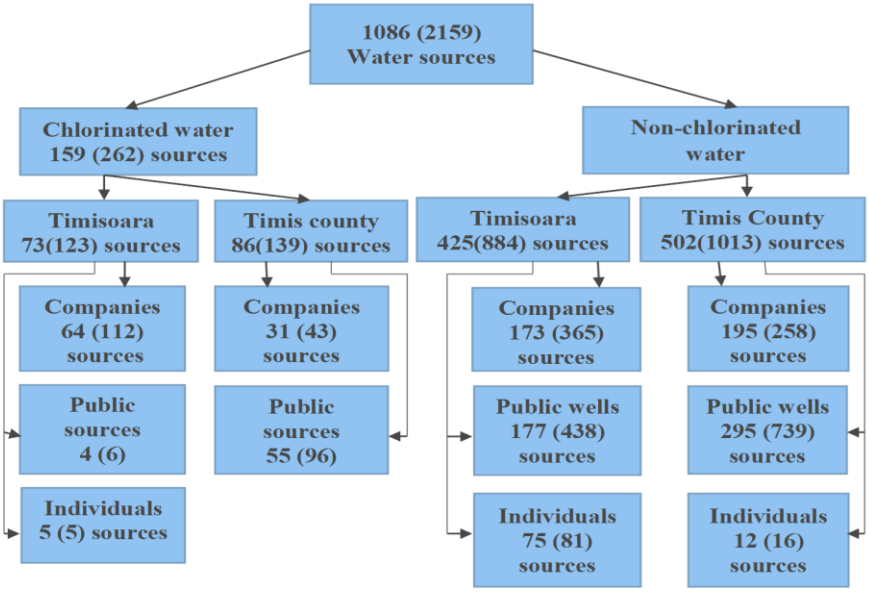

Fig. 1. Study sample of the water sources (number of water tests in brackets)

The method consisted of an observational case-study (combined approach: cohort and cross-sectional) of the chemical composition of drinking water (usual parameters: pH, turbidity, conductivity, ammonia, nitrites, nitrates, chlorides, residual chloride, total hardness, iron, manganese, and oxidability), in Timis County and Timisoara, Romania from 01.01.2016 to 31.12.2017. The methods of analysis and maximum admitted concentrations in accordance with law 458/2002 republished (2011) (3) are mentioned in the PHDT analysis bulletins and they are in accordance with national guidelines (4). Statistical analysis (mean, median) was performed with the aid of *SPSS version 20.0* software.

The agreement to access primary evidence, while keeping this evidence confidential and respecting the personal data protection law of the owners, was asked and received from the Leadership of the Public Health Direction Timis. The agreement of the "Victor Babes" University of Medicine and Pharmacy's Ethical Commission was requested and obtained for this study.

RESULTS

Chemical parameters in drinking water for entire sample

Mean concentrations of the chemical parameters of water demonstrated after water tests analysis can be seen in tab. I. First result that could be noticed is that the

majority of the water chemical parameters fell under the Maximum Admitted Concentrations (MAC), except for manganese and iron (for non-chlorinated water in both areas) and ammonia (for chlorinated water in Timis County) (tab. I).

First key issue identified was **manganese mean concentrations** that frequently surpassed MAC (50µg/L) in non-chlorinated water, for companies, individual and public wells, in both areas Timisoara and Timis County (tab. I).

TABLE I.

Mean concentrations of the chemical parameters of water for the entire sample

T- Timisoara, TC-Timis County; C-companies; P-public sources; I-Individuals;
1-Chlorinated; 0-Non-chlorinated.

Iron mean concentrations were proven to be another problematic issue that surpassed MAC (200 µg/L) in public wells in Timis County (207 µg/L) and in public wells in Timisoara (495 µg/L), in non-chlorinated water (tab. I). Another parameter that surpassed MAC (0.5mg/l) was **ammonia mean concentrations** in chlorinated water, in Timis County, for companies (0.71 mg/l) and public sources (0.72 mg/l) (tab. I). Ammonia exceeded MAC in Timis County (rural) (0.55 mg/l) in public water sources, too. Another aspect that needs attention for these key issues is **the number of water tests** for each chemical parameter. In Timisoara from 444 (438 non-chlorinated water) water tests in public wells, only 269 were harvested for manganese, 274 for iron and 442 for ammonia. There were public wells that were not monitored for manganese (169), and iron (164). In Timis-County from 741 public sources (657 non-chlorinated water), only 544 were harvested for manganese, 716 for iron and

527 for ammonia. Only the monitored water sources have been considered in this analysis.

DISCUSSION

Although drinking water quality is regulated and monitored in many countries there is a need to review standards, to assess accurately the population exposure through robust epidemiological studies (5). In the performed study the resulted sample was complex, and it was a misbalance between monitored chlorinated and non-chlorinated water sources. First obtained results offer us a picture of the chemical quality of drinking water. Therefore, averages of the majority of chemical parameters were included in the intervals prescribed by guidelines. It is necessary to consider in this kind of assessment not only one chemical, but especially the mixture of contaminants, particularly at low exposure range (6).

The resulted key issues in the performed study were **manganese, iron and ammonia**. Usually manganese intake from drinking-water is low (20 μg/L) and it could be provided from rocks and soil or from water pollution of improperly constructed wells. Manganese could also be provided for organism through food and air (at different order of magnitude milligrams and nanogram, respectively) (7). Manganese mean concentration and median were found as very high in Timisoara public wells (majorities of the tests performed for manganese surpassed the MAC-50 μg/L). Elevated levels of dissolved manganese are often found in deep wells. Since 2011, the World Health Organization considered manganese concentrations in drinking water were not necessary to derive a formal guideline value, the maximum admitted concentration (400 μg/L) considered before being too high to adequately protect public health (8). In the performed study public wells with the resulted mean concentrations of manganese higher than 200 μg/L can be found in the entire city of Timisoara. In Timis County very high concentrations of manganese were also found. The enrichment of soil with manganese resulting from industrial inputs may threaten human beings (through environmental factors: water, food and air) (9). In research literature there are described different ways to remove manganese from drinking water by physical, chemical, and biological processes or by a combination of these methods (10).

Another discovered key issue of drinking water in rural Timis County (in non-chlorinated water and in public wells) was the **iron** concentration, recorded with a mean concentration that surpassed MAC (200 μg/L) and a median that fell in the admitted interval. Public and individual wells water that exceeded MAC for manganese, iron and other metals proved to be with reduced quality in another study (11). Iron mean concentration was also high in 23 public wells from Timisoara, but the calculated median was included in the admitted interval. Both substances (iron and manganese) impart a strong metallic taste to the water and both cause staining. Water rich in iron and/or manganese may appear initially without color, but orange-brown (iron) or black (manganese) stains or particles quickly appear as the water is exposed to oxygen (12). A better monitoring of public wells was noticed in Timis County than in Timisoara (great number of missing tests for manganese and iron determination

in water). In literature research iron and manganese proved to have an impact on human health (possible mild cognitive impairment and Alzheimer disease) (13), and not only the effect of altering sensorial (taste) and physical (color) quality of water.

Ammonia was found in high concentrations in chlorinated water in Timis county (urban: Lugoj and Faget) and in non-chlorinated water, in public wells from Lugoj after 2 successive determinations (March and July) in 2016. While ammonia itself is not noxious, it is an indicator of organic water pollution. Mean concentrations of ammonia in the majority of sources from Timis County and Timisoara fell under MAC (0.5 μg/L). In deep wells ammonia concentrations could increase in an anaerobic environment. In surface water the aerobic environment decreases ammonia. In another study nitrification (ammonia being transformed in nitrites) was analyzed in the sediment of a surface drinking water supply in Hong Kong (Dongjiang River) and it was frequently detected (14).

The study's results represent a starting point for future investigation of the factors that determine such high concentrations of manganese in public wells from Timisoara, of iron in public wells from (rural) Timis County and of ammonia in chlorinated water and public wells from Lugoj in 2016. A better monitoring of public wells from Timisoara resulted as being necessary. A limit of this study is that it is an observational one.

CONCLUSIONS

Drinking water supplied in Timis County and Timisoara over the 2016-2017 period corresponded as chemical composition to recommended guidelines for most usual chemical parameters, except manganese, iron and ammonia.

Manganese was found as a key issue with the chemical properties of drinking water in Timisoara and in certain villages from Timis County. Implications of this found key issue are important due to the extensive use of public wells by the population of Timisoara.

Iron was another key issue with the drinking water chemical concentrations in Timis County (rural) and in Timisoara public wells. Implication of this key issue is that its presence could be associated with color change and high concentrations of other chemicals, such as manganese in public wells from Timisoara.

Last identified key issue was ammonia in Timis County (urban - Lugoj), in chlorinated (companies and public sources) and non-chlorinated water (public wells).

Public well monitoring and control was discontinuous, and it was better performed in Timis County than in Timisoara. New investigation regarding the causes of these key issues and their health impact will be necessary as well as an intervention plan to solve them.

MAGNITUDE AND VARIATION OF THE MANGANESE, IRON AND AMMONIA IN DRINKING WATER FROM TIMIS COUNTY, ROMANIA (Abstract): The **aim** of the performed study was to investigate the magnitude and variation of the manganese, iron and ammonia, as identified key issues, considering presence/absence of chlorination, area, property and time when the samples were collected. **Material and methods:** The observational case-study was conducted for 2 years (2016-2017) on a sample of 1,086 water sources in Timis County. A statistically significant difference ($p<0.001$) resulted between chlorinated and non-chlorinated sources for manganese and for iron mean-concentrations, Timisoara and Timis County (rural) public wells for manganese and for iron mean concentrations, and public and companies` wells in Timisoara for manganese. **Results:** Statistically significant differences of ammonia mean concentrations were also found between Timis County and Timisoara for public wells ($p<0.001$) and for companies ($p=0.002$), in non-chlorinated water. Calculated medians of manganese concentrations in well water were high in Timisoara (200 µg/L) and in Timis County (95 µg/L) and exceeded MAC (50 µg/L). The highest concentration of manganese (500 µg/L) was recorded in Timisoara, in 2016. Median of iron (93 µg/L) concentrations in public wells in Timis-County (rural) was much higher than median (50 µg/L) in public wells in Timisoara. Both median values didn`t exceed MAC (200 µg/L). Still, the highest mean concentration of iron (3,780 µg/L) was found in a public well from Timisoara, in 2016. Median of ammonia concentrations in public wells (non-chlorinated water) in Lugoj (0.6 mg/L) also surpassed MAC (0.5 mg/L). **Conclusions:** excessive concentrations of manganese, iron and ammonia were found in drinking water in Timis County, with significant variation in space, time and depending on property and chlorination. **Keywords:** MAGNITUDE, VARIATION, IRON, MANGANESE, AMMONIA, OBSERVATIONAL CASE-STUDY.

Drinking water is an important element of the diet for the population served and its chemical composition could have a strong impact on health. Health effects due to the modified chemical quality (heavy metals or fluoride) of drinking water were demonstrated in numerous studies (1, 2) with a special approach in the area of inorganic arsenic (3, 4). Drinking water supply in Timis County is provided from surface and groundwater, through central and local systems of water treatment. Key issues (excess of manganese, iron and ammonia) were identified in drinking water in Timis County in a previous study (5). The aim of the performed study was to investigate the

magnitude and variation of the manganese, iron and ammonia considering concentration levels, water chlorination and non-chlorination, areas, property (companies, public and individual) and time when the samples were taken.

MATERIAL AND METHODS

This case-study is based on 2159 water tests taken from 1086 water sources over the two years period of 2016 and 2017. The case-study investigated water sources disinfected with chorine and water sources not disinfected with chorine, from Timisoara and Timis County. These different water sources are monitored by the Public Health Department of Timis and serve individuals, companies, and the general public.

Magnitude and variation (depending on area, time, property and chlorination) of the three key issues (high concentrations of manganese, iron and ammonia, in Timis County and Timisoara) identified in a previous study (5) were analyzed considering the same data base. The sample structure can be seen in first figure.

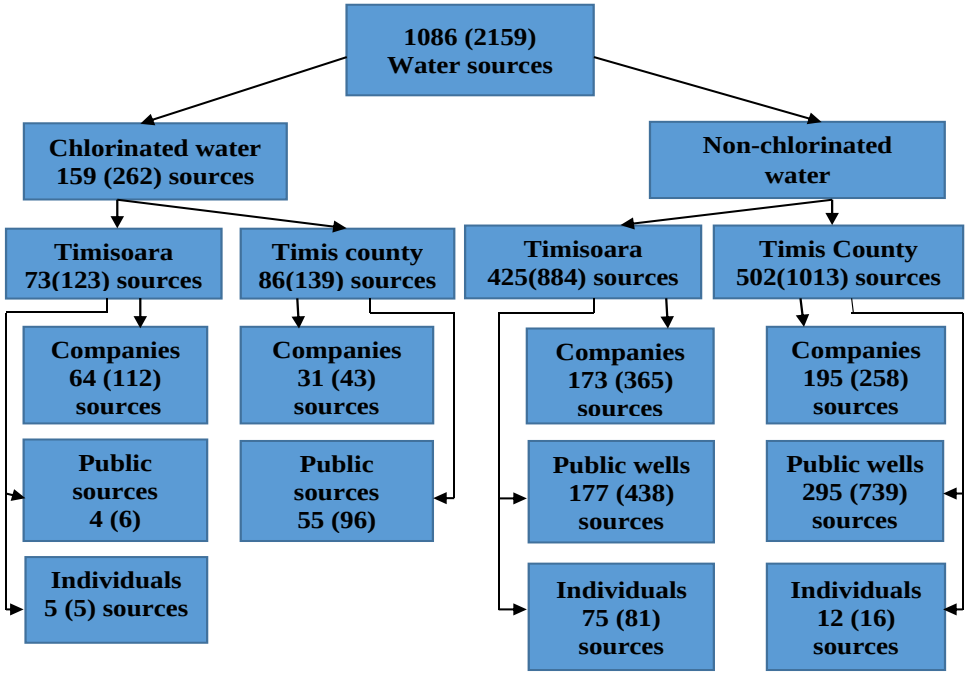

Fig. 1. Study sample of the water sources (number of water tests in brackets)
Retrieved from C. Petrescu, 2022 (5)

Water tests were performed once (cross-sectional) or several times (cohort) for all the variation types considered inside the chosen sample. A misbalance between the numbers of chlorinated and non-chlorinated water sources was noticed inside the sample, the real number of chlorinated water sources being much higher. The methods of analysis and maximum admitted concentrations of manganese, iron and ammonia

were in accordance with national guidelines (6).

Statistical analysis (mean, median, t-test for independent samples) was performed with the aid of *SPSS 20.0* software. The t-test for independent samples was used to compare the chemical parameters' average concentrations among the considered sample elements. Median and mean concentrations were considered when we analyzed magnitude and variation of the key issue parameters. All the necessary approvals (data protection law and ethic agreement) for this study were requested and received from the leadership of County and from the "Victor Babes" University of Medicine and Pharmacy Timisoara's Ethical Commission.

RESULTS

A comparison of the chemical parameters` mean concentrations (T test for independent samples) considering chlorination, area and the property revealed statistically significant differences of the identified key issues (5) between (tab. I):

TABLE I.

Comparison results of the averages of chemical parameters between the considered sample elements (number of water tests in brackets)

- **Chlorinated and non-chlorinated water** (manganese and iron higher in non-chlorinated water);
- **Timisoara and Timis County** (rural) for chlorinated water in companies (iron higher in Timisoara) and for non-chlorinated water in companies (ammonia - higher in Timis County) and in public wells (manganese higher in Timisoara and iron and ammonia higher in Timis County);
- **Public wells and Companies** with non-chlorinated water in Timisoara (manganese higher in public wells);
- **Public and Individual wells** with

non-chlorinated water in Timisoara (manganese higher in public wells);

- **Companies and Individual wells** with non-chlorinated water in Timisoara (manganese higher in individual wells) (tab. I). A limit of this statistical analysis is the different number of water tests for different types of sources.

Magnitude and variation of Manganese in drinking water

Calculated medians of manganese concentrations in well water were high in Timisoara (200 µg/L) and in Timis County (95 µg/L). Both median values exceeded MAC. In Timisoara public wells, in 145 from 269 water tests manganese concentrations exceeded 200 µg/L. Only 24 tests fell under national guideline standards (50 µg/L). Spatial distribution of manganese concentrations in public wells from Timisoara could be seen in figure 2.

The highest mean concentrations of manganese in public wells from Timisoara were found in the following streets: Podgoriilor (500 µg/L-1water test), Piata Unirii (450 µg/L-1 water test), Petofi Sandor (400 µg/L -3 water tests), and Tacit (367 µg/L -3 water tests) (fig. 2). In several localities in Timis County (14 from 502 water sources) were also recorded high concentrations (over 200 µg/L) of manganese, with the highest values in: SanMihaiu German (483µg/L), Utvin (325µg/L), Mosnita Noua (300 µg/L) and Nemesti (283 µg/L). Manganese concentrations exceeded MAC and recorded high monthly concentrations in public wells in Timisoara, in April (500 µg/L), June-August (234 µg/L, 218 µg/L and 216 µg/L), November (228 µg/L) and December (155 µg/L) in 2016, and in March-June (209 µg/L, 163µg/L, 201 µg/L and 250 µg/L) in 2017.

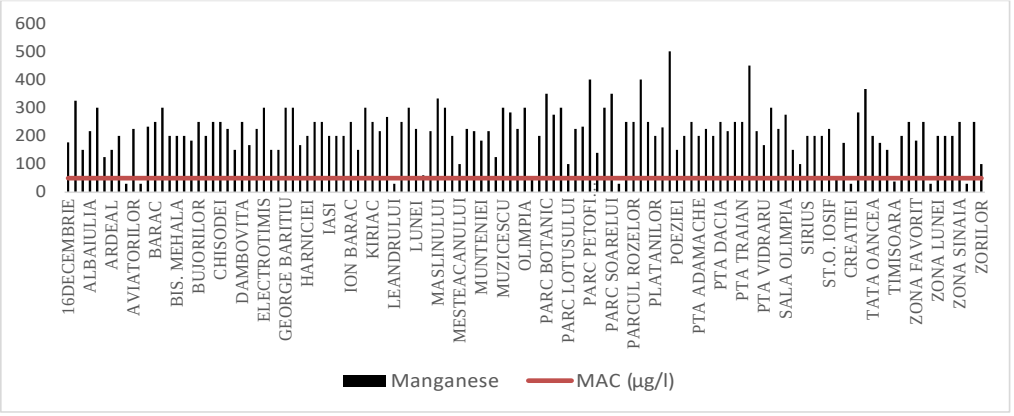

Fig. 2. Spatial distribution of the manganese mean concentrations (≥ 50µg/L) in public wells from Timisoara

Magnitude and variation of Iron in drinking water

Median of iron (93 µg/L) concentrations in public wells in Timis County (rural) was much higher than median in public (50 µg/L) and individual (50 µg/L) wells in Timisoara. Medians of iron in Timis County and in Timisoara did not exceed MAC. In (rural) Timis County public wells, in 207 from 657 water tests iron mean con-

centrations surpassed 200 µg/L. Spatial distribution of iron mean concentrations (≥200 µg/L) in public wells from Timis County can be seen in figure 3.

The highest mean concentrations of iron were found in the following villages in (rural) Timis County: Bazosu Nou (1,720 µg/L - 5 water tests), Mosnita (1,715 µg/L -water pollution -3,760 and 3,420 µg/L and other 9 water tests under 50 µg/L), SanMihaiu German (1,730 µg/L- water pollution 4,580, 680, 410 µg/L in 3 water tests) and Grabati (1,195µg/L -water pollution – 1,710, 1,560 and 1,420 µg/L and 90 µg/L in 4 water tests). Still the mean concentration was 176.7µg/L and the median was 71 µg/L, when considered all public wells from Timis County. There were no missing water tests.

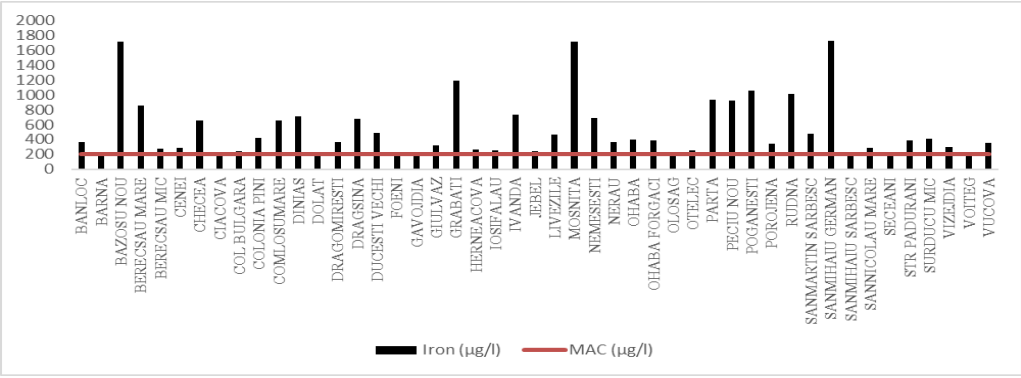

Fig. 3. Spatial distribution of the iron mean concentrations (≥ 200µg/L) in public wells from (rural) Timis County

In Timisoara the number of water tests with iron higher than 200 µg/L was 23, with the highest mean concentrations in 3 public wells: Podgoriilor street (3,780 µg/L), Clabucet Park (1,969 µg/L), Rozelor Park (1,520 µg/L). It is interesting that the levels of manganese were also high in these wells (500, 350, 350 µg/L, respectively). When we considered comparatively the mean and median values of iron in Timisoara for public wells, we noticed a great difference: mean - 95.35µg/L; median-40 µg/L, due to the presence of these very high values in few places.

Iron monthly concentrations were high in public wells in Timis County in January (885 µg/L), February (460µg/L) and July (393 µg/) in 2016, in July (200 µg/L), August (314 µg/L) and December (493 µg/L) in 2017. In May 2017, high monthly concentrations of iron (436 µg/L) were recorded in Timisoara.

Magnitude and variations of Ammonia in drinking water

Ammonia was found with high mean concentrations in public wells (non-chlorinated water) in Lugoj (0.96 mg/L). Medians of ammonia concentrations in public wells (non-chlorinated water) in Lugoj (0.6 mg/L) and in Timis County - rural (0.4 mg/L) also indicate ammonia excess in Lugoj. Ammonia regarding the chemical composition of the drinking water supply in Lugoj (44 public wells and 74 water tests) recorded the highest monthly concentrations in March (0.94mg/L) and July (1.02 mg/L) 2016.

DISCUSSION

In the performed study groundwater sources belong to the city or town halls, companies or individual people. First obtained results offer us a picture of the significant differences of the identified key issues (5) between chlorinated and non-chlorinated water, Timisoara and Timis County, companies, public and individual sources. The spatial and temporal approach was proven to be associated with the aquifer types and to be effective and necessary for correctly measuring or estimating the population's exposure to the tested chemicals (7). Manganese and iron mean concentrations and medians were found to have significant spatial and temporal differences, chlorination and the water ownership being also important variation factors. In research literature there is described a way to remove manganese from drinking water by using of oxidant substances (8), such as chlorine that explain partially the difference of manganese concentration between chlorinated and non-chlorinated water that was shown in the performed study. Magnitude of chemical compounds concentrations was high in public wells from Timisoara for manganese and iron (certain wells), in public wells from Timis County (rural) for iron and manganese (certain wells) and in Lugoj for ammonia in public wells and disinfected water (certain places). In 2016, seasonal variation indicates high monthly concentrations along entire year for manganese (no variation) and first part of the year for iron, and during the spring and summer for ammonia. In 2017, high monthly concentrations were found during the spring and the summer for manganese and during the second part of the year for iron. A study of the seasonal and spatial variability of anthropogenic and natural factors performed in China revealed as determinants for groundwater parameters: water-rock interaction, geogenic iron and manganese, agricultural pollution and organic pollution (9). Another study showed that residents were more willing to accept high metal (manganese and iron) concentration than international guidelines assume (10). In Timisoara a great part of population seems to prefer groundwater, thus explaining the great number of wells used free by-passing people, by individuals or companies. In Timis County (rural) the population has to use groundwater, this being the main source of the water supply.

A limit of this study is that it is an observational one.

CONCLUSIONS

In conclusion, the magnitude as the very high concentrations of the manganese, iron and ammonia, considered as key issues of drinking water supply, and the variation in the concentration of these key elements depend upon the presence or absence of chlorination, the area, property and time of the sampling. Very high concentrations of manganese, iron and ammonia were found in certain public wells from Timisoara, Timis County (rural) and Lugoj. During 2016 the levels of these key issues concentrations were higher than in 2017.

NEWS

THE USE OF SELF-ADHESIVE CEMENTS IN THE ADHESION OF FIBER POSTS AFTER THE APPLICATION OF *EDTA*

The objective of this study was to evaluate the effects of the application of EDTA at different concentrations such as 17%EDTA and 24%EDTA on the parietal dentine before the use of a self-adhesive resin cements: RelyX U200 and Multilink Speed. This type of the cements is used for the adhesion of fiber post which are indicated in the reconstruction of teeth with extensive coronal destruction. This study was performed on 78 extracted human single-rooted premolar teeth, divided in six groups, also ten roots of each group were used for bond strength and three roots for microhardness evaluations. The data obtained were statistical analyzed by two-way ANOVA and post-hoc Turkey's test (α=0.05). The use of EDTA at different concentrations is not recommended as pretreatment for fiber post cementation using self-adhesive cements (Gruber YL, Jitumori RT, Bakaus TE, Reis A, Gomes JC, Gomes GM. Effect of the application of different concentrations of EDTA on the adhesion of fiber posts using self-adhesive cements. *Braz Oral Res* 2020; 35: e012 / doi: 10.1590/1807-3107bor-2021.vol35.0012).

VALIDATION OF THE ROMANIAN VERSION OF MULTIPLE SCLEROSIS QUALITY OF LIFE (MSQOL-54) INSTRUMENT

VALIDATION OF THE ROMANIAN VERSION OF MULTIPLE SCLEROSIS QUALITY OF LIFE (MSQOL-54) INSTRUMENT (Abstract): **Aim**: To validate the Romanian version of MSQOL questionnaire. **Material and methods**: The questionnaire was translated and culturally adapted in the Romanian space for the Romanian population and the questionnaire was validated in 50 patients with multiple sclerosis (MS) at the Neurology Clinic at of the Iasi Rehabilitation Hospital. The following indicators were analyzed: Cronbach's alpha coefficient, Pearson's (r) correlation coefficient, used to investigate the relationship between the composite scores and the main clinical and demographic variables, and the Bartlett Sphericity Test, which shows the correlation between the questionnaire items. **Results**: The psychometric standards met, and the general demographic data are illustrated by the following results. The group consisted of 50 patients, 35 women (70.0%) and 15 men (30.0%), mean age 39.76 ± 10.493 years, age range 18 to 65 years old, with no significant gender differences between the sexes (p = 0.627). Significance level of the Bartlett Sphericity Test, p = .000 - which shows that the items in of the questionnaire are correlated with each other. The Pearson correlation coefficients, all correlation coefficients obtained are statistically significant and moderate or strong in intensity. Median EDSS score was 3 in women, 4 in men, total score was 3. **Conclusions**: From now on, this adequate psychometric questionnaire will which allows an accurate measurement of quality of life (QoL) in MS patients with multiple sclerosis which is from now will be available for all medical professionals dealing with MS patients in Romania. **Keywords:** MULTIPLE SCLEROSIS, DEMYELINATING DISEASE, MSQOL54, VALIDATION PROCESS.

Multiple sclerosis (MS) is chronic immune-mediated of the central nervous characterized by neurodegeneration and neuroinflammation. The main consequence of this processes is the progressive alteration of neuronal transmission, clinically manifest through a wide variety of heterogeneous symptoms (1).

Focal demyelinating lesions are highlighted by magnetic resonance imaging (MRI) as a technique of high accuracy for the lesions detection. MS is the most com-

mon cause of primary non-traumatic neuromotor disability in young adults (2).

Epidemiological data shows that an estimated 2.3 million MS population is living worldwide, with the higher prevalence of multiple sclerosis in Europe and North America and a lower prevalence in sub-Saharan Africa and East Asia. The prevalence of MS is 30-80/100,000 among European population and around 40/100,000 in Romanian population (3, 4). The mean age of diagnosis is 32 years and females are twice as likely to live with MS as males. The lowest incidence is recorded in the equatorial regions, less than 1/100,000 (5).

Nowadays there are a multitude of available quality of life instruments in MS (HRQoL): Hamburg Quality of Life Questionnaire in Multiple Sclerosis (HAQUAMS), Functional Assessment of Multiple Sclerosis (FAMS), Multiple Sclerosis Quality of Life Inventory (MSQLI), Multiple Sclerosis International Quality of Life (MUSIQOL), and Multiple Sclerosis Impact Scale (MSIS). All these scales are necessary for both clinicians and patients to customize the medical care plan and, also, to improve doctor-patient communication (6).

The validation of the MSQOL-54 questionnaire is useful both in current clinical practice and research, the aim being to find out if this psychometric instrument reliably and validly measures the level of quality of life in a population in a specific culture (7). At this point of time only MSQOL-54 and MSQLI contain a series of more specific questions with the role of highlighting both the clinical manifestations and the therapeutic management (8).

MSQOL-54 questionnaire is a multidimensional health-related QoL measure that combines both generic and MS-specific items into a single instrument for the multiple sclerosis patients. It is a structured, self-report questionnaire that the patient can generally complete with little or no assistance, which includes eight elements that measure the physical components and five elements that measure the mental component related to QoL (9).

Currently the MSQOL 54 questionnaire is not validated in Romanian language. At the present time, physicians and researchers have to use the original English version which is a difficult process for most of the patients. Our goal is to translate and culturally adapt the specific MSQOL-54 instrument, pursuing the validation of the Romanian version. In this process of questionnaire validation our objective is to adapt it to the Romanian cultural, social, religious and linguistic space. In our study we focused on the evaluation and the assessment of the quality of life in MS patients using the MSQOL 54 questionnaire (7).

MATERIAL AND METHODS

Baseline characteristics of the population

To be eligible for this study, the patients had to meet the following inclusion criteria: MS diagnosis according to McDonald 2017 criteria; age over 18 years; EDSS (The Expanded Disability Status Scale) score >1. Exclusion criteria were patient's refusal to participate in this study, patient with terminal cancer, terminal illness, or any other severe diseases that could affect QoL and mental health conditions associated with inability to discern and consent to participate in this study.

The investigators were trained how to correctly apply the questionnaire and to calculate the final score. We took into consideration the possible confusion that may be encountered in the application of the MSQOL54 questionnaire due to the slight possibility of patient’s lack of correctly understanding the terminology. To avoid this specific bias due to patients’ incorrect

terminology understanding, the questionnaire was completed under the close supervision of a research team member.

The questionnaire validation process is performed according to the questionnaire validation methodology. We have obtained author's consent for the and use of the questionnaire in this research paper and its validation. The translation process was conducted as follows: translation from English into Romanian, two versions by two different translators, then the translation from Romanian into English by a native English speaker who also speaks Romanian. The validation process is conducted on a group of 50 subjects diagnosed with MS at the Neurology Clinic of the Iași Rehabilitation Hospital who met the inclusion/exclusion criteria and agreed to participate at the time of their presentation to the clinic for various care related problems.

Statistical analysis

The data were collected in a database created in Excel 2010 (Microsoft Corporation, USA) and statistically processed using the *SPSS version 23.0* (Statistical Package for the Social Sciences).

The following indicators were analyzed: demographic data -median, Min-Max, SD (women/men; age, level of education; EDSS score); Cronbach's alpha coefficient (α) -subscale; Kaiser-Meyer-Olkin (KMO) statistics-subscale correlations; Bartlett's sphericity test-subscale correlations) (9).

RESULTS

General characterization of the study group: the group consisted of 50 patients, 35 women (70.0%) and 15 men (30.0%), with mean age of 39.76 ± 10.493, age range from 8 to 65 years old, with no significant differences between the sexes (p = 0.627), first table. Half of the patients had high school education, two primary school education, and the remaining patients higher education.

The average EDSS score was 4.302 ± 6.9326, with scores ranged between 1.0 and 7 slightly higher in women than in men, although even in this case the difference was not statistically significant (p = 0.130). This study shows that 84.0% of patients had EDSS <5.5, 4 patients (8.0%) had an EDSS score between 5.6 ÷ 6.5, in one patient (2.0%) EDSS score was between 6.5 ÷ 8 and in another patient (2.0%) the EDSS score was 8 (tab. II).

TABLE I.

Age of the subjects included in the study. Baseline characteristics of the study population

Sex	N	Mean	Std. Deviation	Std. Error of Mean	Minimum	Maximum	Median
F	34	39.26	10.509	1.802	18	64	38.50
M	15	40.87	10.736	2.772	25	65	44.00
Total	49	39.76	10.493	1.499	18	65	39.00

TABLE II.

EDSS score (The Expanded Disability Status Scale) of the study population

Sex	N	Mean	Std. Deviation	Std. Error of Mean	Minimum	Maximum	Median
F	33	4.500	8.3423	1.4522	1.0	50.0	3.000
M	15	3.867	1.4075	.3634	2.0	6.0	4.000
Total	48	4.302	6.9326	1.0006	1.0	50.0	3.000

MSQOL-54 questionnaire has 14 quantitative 0-100 scales, based on them 2 global scores being calculated: the physical health component, respectively the mental health component.

The Kaiser-Meyer-Olkin Measure of Sampling Adequacy, a statistic that indicates the variance of the investigated variables, caused by the identified factors, had a value of 0.868, close to 1, which means that factor analysis is adequate. The same was true for the significance level of Bartlett Sphericity Test, p = .000 - which shows that the items in the questionnaire are correlated with each other (tab. III).

TABLE III.

Kaiser-Meyer-Olkin Measure and Bartlett's Test of MSQOL-54 questionnaire.

Kaiser-Meyer-Olkin Measure of Sampling Adequacy.	0.868
Bartlett's Test of Sphericity	Approx. Chi-Square 330.559 df 66 Sig. .000

The Pearson correlation coefficients between the used scales and the two components, the physical and the mental, were also calculated to check for correlations. All correlation coefficients obtained were statistically significant and moderate or strong in intensity, which on the one hand shows that the two global indicators are correctly defined, and, on the other hand, that the scales are interlinked, so the questionnaire is valid (tabs. IV and V).

The high values seen in this column show that the scales are well correlated - the weakest correlated being for "Sexual function" scale, with a communality of 0.482.

The extracted communalities are estimates of the variability of the scales explained by the identified factors. In this case high values should be obtained; low values are indicating the scales that are not satisfactorily covered by the factorial solution (percentages above 50% are generally acceptable). In our case, this category includes "Sexual function" (0.366), "Cognitive function" (0.475) and "Overall Quality of Life" (0.488) (tab. VI.)

Cognitive function	.556	.475
Health distress	.701	.634
Sexual function	.482	.366
Overall Quality of Life	.555	.488

DISCUSSION

Clinical validity of the scales was assessed by comparing the mean values of the scores recorded for the demographic characteristics of the group: sex, background, level of education, EDSS score, and treatment (10). Parametric tests (t-Student and ANOVA) were used to make the comparisons when the normal distribution law occurred or when the data were normally distributed, and non-parametric tests (Mann-Whitney and Kruskal-Wallis) were otherwise used.

In general, most of the investigated scores were higher in men than in women, with a few exceptions: Role limitations – physical, Health perceptions, Social function, Sexual function and Satisfaction with sexual function. The observed differences are quite important, but they reach statistical significance only in the case of Cognitive function scale, with higher values in the male than in female patients and Satisfaction with sexual function scale, with higher values in women (fig. 1).

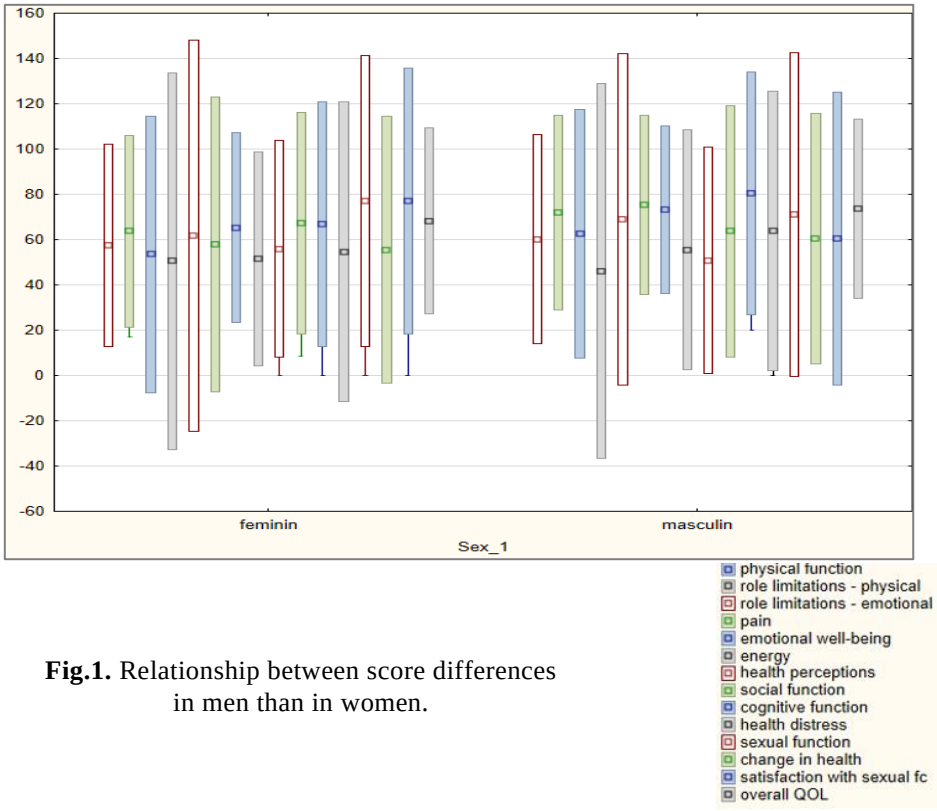

Fig.1. Relationship between score differences in men than in women.

We have also found a tendency of Physical Health Composite (PHC), mental health composite (MHC), and overall quality of life (QOL) to increase as patients have a more advanced level of education (this is the case of Physical Health Components. Mental Health Components, Change in health and Overall Quality Of Life) / that the higher the education level the higher the scores on Physical Health Composite (PHC), mental health composite (MHC), and overall quality of life (QOL); however, the differences between the 3 categories are not statistically significant (fig. 2).

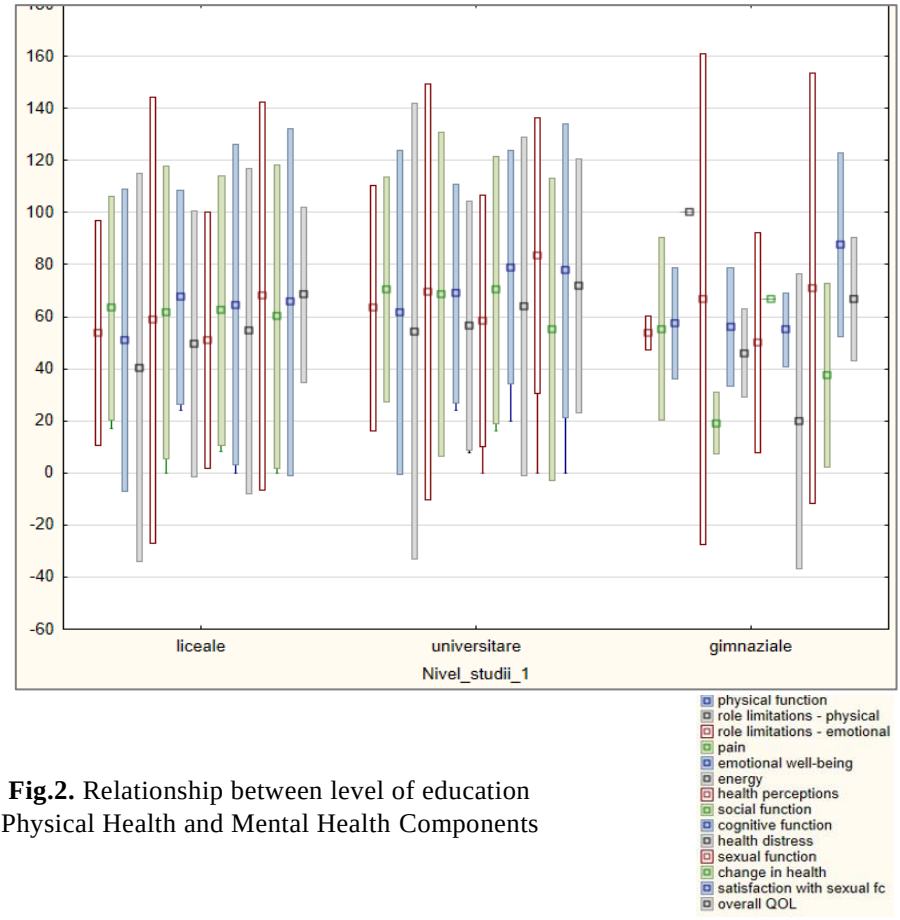

Fig.2. Relationship between level of education Physical Health and Mental Health Components

On the other hand, the scores tend to decrease as EDSS score increases, but even in this case the variations do not exceed the statistical significance threshold. One possible explanation is that we could only compare the EDSS categories <= 5.5 (the most numerous in the group) and EDSS <= 6.5 (4 cases) for in which the scores were quite high; for the other 2 EDSS categories we only had one patient so, no statistical tests could be applied. There was a significant decrease in all scores in the patient with EDSS> 8, but the analysis could not go deeper because only one study patient presented this characteristic (fig. 3).

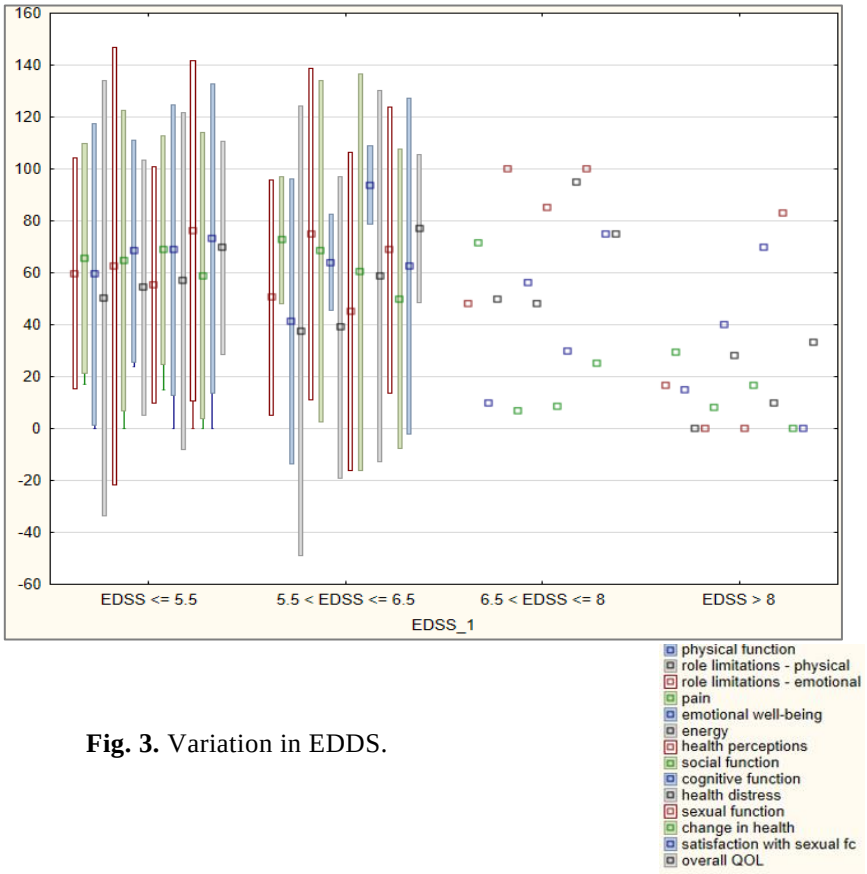

Fig. 3. Variation in EDDS.

In this study, the correlation between the scores on the MSOQL 54 questionnaire and the clinical and demographic factors used, such as age and EDSS score did not show a significant correlation (11). Similar results were found in the validation study of this questionnaire in Turkey, with no significant correlations between the following scores: age, sex, level of education (12). Also, in this study the male patients showed a 100% rate of sexual satisfaction. Despite this discordant result. medical data showed an increased rate of sexual dysfunction problems, but in this study, the females showed a high rate of sexual satisfaction. This aspect underlines the difficulty of talking about male sexual function, which can be attributed to cultural and social perceptions or characteristics (12).

In our study younger patients with a higher level of education scored higher on the mental and physical components, while the MSQOL-54 validation study in Bosnia and Herzegovina showed that younger patients with a higher level of education, shorter disease duration had lower scores in some areas of HRQoL: such as role limitations due to physical problems, physical health, and role limitations due to emotional problems (13).

CONCLUSIONS

This adequate psychometric question-

naire which allows an accurate measurement of QoL in MS patients is from now on available for all medical professionals dealing with MS patients in Romania. Using this instrument in medical practice could provide additional information about treatment effectiveness and the impact of this disease on the physical and mental components of QoL in these patients.

This study demonstrates that the Romanian version of MSQOL-54 is well accepted by MS patients and this instrument will become a routine in medical practice.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

DESIGN AND *IN SILICO* STUDIES ON DIFFERENT DENGUE VIRAL PROTEINS OF SOME COMPOUNDS BASED ON ACETOPHENONE SKELETON (Abstract): **Aim:** In this study, we performed the evaluation of anti-Dengue potential of some acetophenone derivatives and diazine with dihydroxyacetophenone skeleton derivatives, using molecular docking approach, as potential candidates for anti-dengue virus drug discovery. **Material and methods:** For this study 20 synthetic ligands were used. Docking studies were conducting using iGEMDOCK (Generic Evolutionary Method for molecular Docking) software. **Results:** The obtained results revealed that all the 20 compounds show good affinity with all the proteins; significant affinity was observed between the tested compounds and Dengue transmembrane domain of NS2A protein. **Conclusions:** The conclusion drawn from our virtual screening and docking result reveals that the investigated compounds have a good binding affinity with most of the proteins and some of they can be used as an effective drugs target for Dengue virus. **Keywords:** BINDING INTERACTION, MOLECULAR DOCKING, DENGUE VIRUS, ACETOPHENONE SKELETON, DRUG DESIGN.

Highly functionalized acetophenone derivatives are an important class of organic compounds which exhibiting interesting biological properties, such as antimicrobial (1) and anticancer activities (2) being a valuable compound for supramolecular or medicinal chemistry (3). In last years, 1,2-diazine derivatives have demonstrated to possess a large variety of biological activities: antihypertensive (4) diuretic (5) antiplatelet (6) cardiotonic (7) anticancer (8) anti-HIV (9) anti-inflammatory (10) antimicrobial (11) anti-tuberculosis (12) etc.

Dengue virus is part of the family *Flaviviridae*, genus Flavivirus (13, 14). The Dengue virus causes a range of clinical manifestations, the most severe forms being Dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS) (15, 16). Currently, there has been no vaccine or effective antiviral drug available against dengue infection. Therefore, many researchers are trying to find an efficient antiviral agent against this virus (17).

There are ten proteins in Dengue virus, three are structural proteins, including

envelope (E), capsid (C) and PreM, and seven are nonstructural proteins. The process of viral replication and pathogenesis of Dengue virus is associated with the seven non-structural proteins, namely NS1, NS2A, NS2B, NS3, NS4A, NS4B, and NS5 (18,19).

NS proteins reshape the inner organization of the cell, mature the polyprotein, replicate the viral RNA and help the virus evade the immune system. Among the seven non-structural proteins, NS5 is the largest protein (102 kDa) that encoded by *Flavivirus* genome (18). NS5 encodes methyltransferase (Mtase) on N-terminal and RNA-dependent RNA polymerase (RdRp) on C-terminal and it can also down-regulate the host immune interferon response (20).

The effective and efficient methods in designing and developing a novel potential drug candidates can be completed through *in silico* approach because the identification of potential drugs can be obtained more quickly (21).

In recent times, computational drug chemistry is proving to be an efficient tool for identification and prediction of compounds that can have anti dengue activity (22). Docking analysis is an important aspect for getting the information on the interaction profile of the protein with the ligands. The interaction of the protein with the ligands is given by the binding energy (23).

The compounds containing acetophenone skeleton and diazine with dihydroxyacetophenone scaffold derivatives have wide interest due to their diverse pharmacological properties. In particular, these biological activities make these derivatives more attractive and testing as novel therapeutic compounds.

As part of our aim in research of biologically active acetophenone derivatives, the free hydroxyl groups attached on the acetophenone ring has allowed us to introduce some radicals that can improve the biological activity. Looking to the medicinal importance of the aceto-phenone skeleton, we performed the evaluation of anti-Dengue potential of some acetophenone derivatives and diazine with dihydroxyacetophenone skeleton derivatives, previously synthesized, using molecular docking approach.

MATERIAL AND METHODS

Chemistry

The synthesis of the target compounds which were used as ligands were previously reported (24, 25). A series of dihydroxyacetophenone were treated with methyl chloroacetate at room temperature. When the reaction occurred in a molar ratio of 1:2, dialkylated derivatives were obtained (**1a-e**). These derivatives lead to the bromo-bisetherificated acetophenone derivatives (**2a-e**) in the presence of copper bromide in a mixture of chloroform/ethyl acetate. In order to obtain cycloimmonium salts, different nitrogen heterocyclic compounds have been treated with halogenated acetophenone skeleton derivatives with increased reactivity (**3a-e** and **4a-e**).

Spectral characterization

In Table I we present the chemical structure and the name for the synthesized compounds. Table II shows some physico-chemical and spectral characteristics of the derivatives. Synthetic pathway of compounds with acetophenone skeleton is presented in figure 1.

TABLE I.

Chemical structure of compounds with acetophenone skeleton (1-4)

Comp.	Structure	Comp.	Structure
1a	 dimethyl 2,2'-((4-acetyl-1,3-phenylene) bis(oxy)) diacetate	**3a**	 1-(2-(2,4-bis(2-methoxy-2-oxoethoxy)-phenyl)-2-oxoethyl) pyridazin-1-ium bromide
1b	 dimethyl 2,2'-((2-acetyl-1,4-phenylene) bis(oxy)) diacetate	**3b**	 1-(2-(2,5-bis(2-methoxy-2-oxoethoxy)-phenyl)-2-oxoethyl) pyridazin-1-ium bromide
1c	 dimethyl 2,2'-((2-acetyl-1,3-phenylene) bis(oxy)) diacetate	**3c**	 1-(2-(2,6-bis(2-methoxy-2-oxoethoxy)-phenyl)-2-oxoethyl) pyridazin-1-ium bromide
1d	 dimethyl 2,2'-((4-acetyl-1,2-phenylene) bis(oxy)) diacetate	**3d**	 1-(2-(3,4-bis(2-methoxy-2-oxoethoxy)-phenyl)-2-oxoethyl) pyridazin-1-ium bromide
1e	 dimethyl 2,2'-((5-acetyl-1,3-phenylene) bis(oxy)) diacetate	**3e**	 1-(2-(3,5-bis(2-methoxy-2-oxoethoxy)-phenyl)-2-oxoethyl) pyridazin-1-ium bromide

Comp.	Structure	Comp.	Structure
2a	 dimethyl 2,2'-((4-(2-bromoacetyl)-1,3-phenylene) bis(oxy)) diacetate	**4a**	 2-(2-(2,4-bis(2-methoxy-2-oxoethoxy)-phenyl)-2-oxoethyl) phthalazin-2-ium bromide
2b	 dimethyl 2,2'-((2-(2-bromoacetyl)-1,4-phenylene) bis(oxy)) diacetate	**4b**	 2-(2-(2,5-bis(2-methoxy-2-oxoethoxy)-phenyl)-2-oxoethyl) phthalazin-2-ium bromide

Molecular docking

Preparation of Dengue viral proteins

The protein data bank (PDB) was used to obtain the three-dimensional structure of the macromolecule. PDB contains large number of proteins which are experimentally determined and stored in this site. The structures are downloaded and saved either in mm CIF or PDB format. Proteins of dengue virus were used for this study. The 3D structure of all the seven proteins were downloaded from PDB and saved in PDB format. The downloaded proteins were viewed in Py-Mol viewer.

Preparation of ligands

The compounds selected from both natural and synthetic sources can be considered as ligands. 20 synthetic ligands were used for this study (tab. I). Ligands were constructed using ChemSketch. The constructed ligands were optimized to add the hydrogen bonds and the obtained structures were saved in mol for docking analysis and named as A, B and C respectively.

Docking study

Docking studies were conducting using iGEMDOCK software. IGEMDOCK (Generic Evolutionary Method for molecular Docking) is a graphical-automatic drug design system for docking, screening and post-analysis. The proteins and the ligands were loaded, and the out path was set. Standard docking parameters were used for docking (population size=200, generations=70 and Number of solutions=2). The docking process was initiated. After the docking process, the best docking pose for the individual ligands can be obtained for all the seven dengue viral proteins. The best binding pose, the binding affinity and the total binding energy values were saved in the output folder. The saved files were visualized in Py-Mol viewer.

RESULTS AND DISCUSSION

Chemistry

The designed dihydroxyacetophenone derivatives (**1a-e**, **2a-e**) and diazine with dihydroxyacetophenone skeleton derivatives (**3a-e**, **4a-e**) were synthesized according to figure 1.The procedures and conditions of the reactions were previously presented (24, 25).

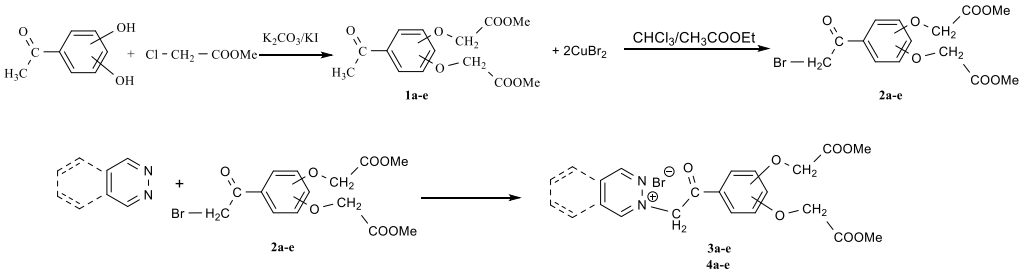

Fig. 1. The reaction pathway in synthesis of the target compounds

***In silico* molecular docking**

Using molecular docking approach, we performed the evaluation of anti-Dengue potential of five bis-etherificated acetophenone derivatives, five α-bromo-bisetherificated acetophenone derivatives and ten cycloimmonium salts with acetophenone skeleton, previously synthesized. So, 20 compounds, which were used as ligands, were selected for this study (tab. I).

The fitness and the interaction profile (the total binding energy, Van der Waal's Force and H-bond energy, in kcal/mol) of the dengue virus proteins with the ligands are presented in tables III-V. The lower energy scores represent better target protein-ligand binding affinity compared to higher energy score.

TABLE III.

The total binding energy (kcal/mol) profile for Dengue virus proteins with the investigated ligands

From tables III-V, the 3D structure coordinates of protein of Dengue virus is optimized and 20 compounds are identified. Their total binding energy was calculated using iGEMDOCK. Evaluations of binding conformation of 20 compounds with dengue viral proteins are performed using iGEMDOCK. From docking study, we listed binding affinity of 20 compounds based on ligand binding energy. The binding pose for each ligand molecule into the dengue viral protein is analyzed and the one having lowest ligand binding energy with these proteins among the different poses are generated. The lower energy scores represent better protein-ligand target binding affinity compared to higher energy score.

The obtained results showed significant affinity between the tested compounds and Dengue transmembrane domain of NS2A protein. NS2A protein, a membrane protein, is one of the proteins found in the replication complex of flaviviruses. This protein possesses specific recognition sites for certain proteases (26). Compound **4b** was found to have the lower ligand binding energy compared to the binding energy at the other analogs for transmembrane domain of NS2A protein (binding energy value = -732.67 kcal/mol),

The amino acid positions for each ligand were studied (Table VII). Interaction analysis of binding mode of compound **4b** for transmembrane domain of NS2A protein revealed that it forms one hydrogen bonds at positions THR(7) with bond energies -8 kcal/mol,

Among the 20 analogs, compound **4a** was found to have lower ligand binding energy than other analogs for Capsid protein (binding energy value = -110.76 kcal/mol), and for NS3 Protease protein (binding energy value = -124.58kcal/mol).

Evaluations of the results showed that, the compound **4a** 2-(2-(2,4-bis(2-methoxy-2-oxoethoxy)phenyl)-2-oxyethyl)phthalazin-2-ium bromide forms one hydrogen bond at positions ARG(41), with bond energies, -12.3kcal/mol. We further analyzed the docked pose for finding the binding mode of compound **4a** into Capsid protein and for NS3 Protease protein to validate the reasonable binding conformations.

Compound **4c** was found to have the lower ligand binding energy for NS5 protein with a value of -133.29 kcal/mol and it appear two hydrogen bonds at positions THR(51) with different bond energies (-9.5 kcal/mol and -3.5 kcal/mol respectively).

For Envelope protein compound **4e**was found to have lower ligand binding energy (binding energy value = -113.81kcal/mol), than other analogs. Compound **4e** 2-(2-(3,5-bis(2-methoxy-2-oxoethoxy)phenyl)-2-oxyethyl)phthalazin-2-ium bromide forms two hydrogen bonds at positions LYS(625) and ILE(618), with bond energies, -3.5kcal/mol.

NS3 protein is a particularly interesting molecular target for antiviral compounds because of it central role in the viral life cycle. Dengue virus NS3 is a multifunctional protein in which the N-terminal 180 amino acids encode a protease that mediates viral polyprotein processing (27). This protein endowed with protease, helicase, adenosine triphosphatase (ATPase) and RNA 5' triphosphatase (RTPase) activities (28).

In examining the binding interaction and position of the compound **4a** with NS3 Protease protein ligand binding site predicted, it was found that two hydrogen bonds are formed, at positions ARG(107) and ASN(105) with bond energies, -4.5 kcal/mol and -7 kcal/mol, respectively.

The lower ligand binding energy for NS3 Helicase protein was proven to be compound **3e**. The evaluation of amino acid positions reveals that this compound, 1-(2-(3,5-bis(2-methoxy-2-oxoethoxy)phenyl)-2-oxyethyl)pyradazin-1-ium bromide, forms two hydrogen bonds at positions ASP(284) and LEU(193).

Dengue virus NS1 is a glycoprotein essential for viral replication with an unknown mechanism (29). NS1 is considered a unique "viral toxin" in dengue disease (30). Compound **4d** was found to have lower ligand binding energy (binding energy value= -130.32kcal/mol), for NS1 protein. The compound **4d** 2-(2-(3,4-bis(2-methoxy-2-oxoethoxy)phenyl)-2-oxyethyl)phthalazin-2-ium bromide forms two hydrogen bonds at positions ARG(336) and SER(228) with bond energies, -6.7 kcal/mol and -3.5kcal/mol respectively.

CONCLUSIONS

Our molecular docking studies explored the possible binding modes of 20 synthesized compounds, as ligands, with different Dengue virus proteins which include capsid protein, envelope protein, NS1 protein, transmembrane domain of NS2A, NS3 protease protein, NS3 helicase protein and NS5 protein. Several interactions were observed between the ligands and the protein binding pocket like the total binding energy, Van der Waal's Force and H-bond energy, in kcal/mol. The obtained results revealed that all the 20 compounds show good affinity with all the proteins; significant affinity was observed between the tested compounds and Dengue transmembrane domain of NS2A protein.

On comparing the binding energy and the binding site residues, we found that all compounds differ either in their binding modes or with the binding site residues for hydrogen bond formation. The conclusion drawn from our virtual screening and docking result was that the compound **4a** has highest binding affinity with most of the proteins and it can be used as an effective drug target for Dengue virus. Though, there are many reports on the *in vitro* analysis of these compounds and its antioxidant properties, but there are no *in silico* studies that predict the binding and active regions especially with these proteins.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

IMPLICATION OF HUMAN FC RECEPTORS POLYMORPHISM IN CHILDHOOD IMMUNE THROMBOCYTOPENIC PURPURA (Abstract)**:** Immune thrombocytopenic purpura (ITP) is the most frequent form of autoimmune disease in childhood, characterized by thrombocytopenia (platelet count $<150 \cdot 10^9$/L) with otherwise normal cell lineages. One of the main mechanisms is the platelet destruction by phagocytic cells, covered by human Fc receptors (FCGR). The FCR family involves 3 classes of receptors: FCGR1A, 1B, and 1C; FCGR2A, 2B, and 2C; FCGR3A and 3B, all present on chromosome 1q23-24. The response to ITP treatment may be influenced by the polymorphism of the FCGR3A gene, which contributes to different levels of destruction of antibody - bound platelets. **Material and methods:** We report the results of FCGR2/3 polymorphic genotypes in 16 children with ITP admitted at the "Sf. Maria" Emergency Children's Hospital, Iasi, Romania, treated with corticosteroids, intravenous immunoglobulin (IVIg) or both, or conservative treatment, with a minimum of one year follow up. **Results:** We identified 9/16 patients with FCGR2C ORF haplotypes, 8 in heterozygous state and one in homozygous state, and 15/16 patients with FCGR2A-His166 variant. While it was previously reported that classical FCGR2C-ORF and 2B.4 variants correlate with the transient form of ITP and a good response to IVIg, in our sample it was present only in 3 patients, who had limited course of disease and a good response to IVIg. 5 patients were heterozygotes for FCGR2C-p.Gln62Trp, all of them developing an acute form, a good response to IVIg and no relapses. Furthermore, it has been demonstrated an association between FCGR genotypes characterized by increased immunoglobulin binding activity (FCGR3A allele V158 and FGCGR3B allele NA1) and chronic children ITP. In our study, only 2/16 patients express NA1 in homozygous state, one of them developing persistent ITP, while the other responded well to the treatment and did not relapse. **Conclusions:** Genetic influences contribute to the pathogenesis of ITP in children and response to IVIg. We evaluated the genetic risk factors in the FCGR2/3 locus that are associated with predisposition to limited course and a favorable response to IVIg in ITP in children. However, confirmation in a larger prospectively recruited cohort of children with ITP is needed. **Keywords:** FCGR POLYMORPHISM, IMMUNE THROMBOCYTOPENIC PURPURA, CHILDREN, PLATELETS.

Immune thrombocytopenic purpura (ITP) is the most frequent form of autoimmune disease in childhood, characterized by thrombocytopenia (platelet count <150 · 10^9/L) with otherwise normal cell lineages. The incidence ranges from 2-8 cases / 100,000 people, with a higher frequency in boys, with maximum between 2-5 years old (1, 2). The diagnosis is based on history, clinical exam, cell blood count, with the elimination of other clinical conditions that may lead to thrombocytopenia - malignancies, immunodeficiencies or immunologic diseases. Most often, the disease is self-limited, having spontaneous resolution in several weeks. However, approximately 20% of children with ITP still have decreased platelet counts 6 months after the clinical onset (1, 3). The main mechanisms explaining thrombocytopenia is the platelet destruction by phagocytic cells. Human Fc receptors (FCGR) are glycoproteins that bind the Fc portion of IgG which links to platelet-specific membrane antigens. Consequently, these platelets are phagocytized by reticuloendothelial cells, that express Fc receptors. The FCR family involves 3 classes of receptors: FCGR1A, 1B, and 1C; FCGR2A, 2B, and 2C; FCGR3A and 3B, all present on chromosome 1q23-24 (1,4). Loss of inhibitory FCGR2B expression, altered function due to single nucleotide polymorphisms (SNPs), or overrepresentation of FCGRs produce a disturbed immunity and subsequent auto-inflammation.

The role of Fc receptors is underlined by the fact that intravenous immunoglobulin (IVIg) treatment and splenectomy are efficient treatment choices, although the mechanism of action of IVIg in ITP is not clear. Several explanations have been proposed, including increased surface expression of FCGR2B, blockade of the Fc receptor for IgG or the acute interaction activating FCGRs on dendritic cells (5). The response to ITP treatment may be influenced by polymorphism of the FCGR3A gene, which contributes to different levels of destruction of antibody- bound platelets (6).

We report the results of FCGR2/3 polymorphic genotypes in children with ITP followed at the "Sf. Maria" Emergency Children's Hospital, Iasi, Romania, during a two-year period.

MATERIAL AND METHODS

We included in the current study all children diagnosed with ITP during a two-year period and a follow up of minimum 12 months. The study was approved by the Ethics Committee of "Sf. Maria" Emergency Children's Hospital, Iasi, Romania (Ref No. 503/08.01.2020). ITP was diagnosed based on platelet count <150·10^9/L. Secondary causes of thrombocytopenia were excluded. Clinical manifestations such as ecchymosis and petechiae, epistaxis, hemorrhagic bullae on the oral mucosa, platelets count, and the therapeutic schemes were recorded. Treatment decision (corticosteroids, IVIg, no treatment) were taken by the individual hematologists, based upon their experience. Bleeding severity was classified according to Buchanan Score (7). We collected blood samples (5 ml into a P100 tube) with informed consent. All patients had a minimum one-year follow-up. Persistent ITP was considered when low platelet count persisted after 3 months of follow up, while chronic ITP - when platelet count continued to remain below the threshold after 12 months of follow up.

The PureLink™ Genomic DNA kit (Thermo Fisher Scientific) was used to extract the genomic DNA, following the recommended protocol. To evaluate both the copy number variations (CNV) and the

SNPs in FCGR 2/3 locus, we performed multiplex ligation-dependent probe amplification (MLPA) with two complementary probe mixes P110 / P111. MLPA probes were designed specifically to cover a distance of 180 kb in the locus FCGR 2/3, located on the long arm of chromosome 1 (1q23.3). For the correct assessment of the CNVs or rearrangements, both probe mixes contain 14 probes, including FCGR2/3 locus and the thermal shock proteins HSPA6 and HSPA7 (fig. 1).

The protocol consisted of denatured 100 nanograms of genomic DNA followed by hybridizing with MLPA probes at 60°C for approximately 20 hours in a SensoQuest thermocycler (Sen-soQuest GmbH, Göttingen Germany). Reference DNA SD038 were used as reference DNA samples. The ligation was done at 54°C for 20 minutes. PCR amplification was performed using Cy5 labelled primers. The fluorescent amplicons were separated by capillary electrophoresis in CEQ 8000 GeXP Genetic Analysis System (Beckman Coulter, USA), and the raw data were analyzed by using Coffalyser.NET V9 software (MRC-Holland, Amsterdam) (8). Because the copy number variation in FCGR2/3 locus, the cut-off values probes were established between 0.8-1.2 for normal copy numbers (from reference DNA) and raised and decreased proportionately for more or fewer copies.

Institutional Review Board Statement. The study was conducted in accordance with the Declaration of Helsinki and approved by the Ethics Committee of "Sf. Maria" Children's Hospital, Iasi, Romania (Ref. No. 503/08.01.2020).

Informed Consent Statement. Informed consent was obtained from all subjects involved in the study.

RESULTS

Sixteen children with ITP, aged 1 to 15 years old (10 boys and 6 girls) were included in the study. 15/16 patients had a clinical onset of the disease following an episode of acute viral infection prior to presentation. All cases presented platelet number below 20000/mmc. The assessment of bleeding severity according to Buchanan score revealed 3 patients with mild hemorrhage (grade 2), 6 with moderate (grade 3) and 7 patients with severe hemorrhage (grade 4). The therapeutic scheme was the following: 5 patients received corticosteroids, 8 patients received corticosteroids associated with IVIg, 2 patients received only IVIg and one patient was monitored without any specific medication. 6 patients developed persistent ITP and none of them progressed towards chronic ITP (tab. I).

Deletions/duplications

The analysis of deletion /duplication in the low-affinity FCGR locus identified one patient with CNR1 type deletion (copy number region 1), including the FCGR2C, HSPA7 and FCGR3B genes (fig. 1) and two patients with CNR4 (fig. 2) that includes the FCGR3B, HSPA7 genes and the fusion between proximal FCGR2B and distal FCGR2C genes.

The presence of the CNR4 duplication (fig. 2) with the fusion between the proximal part of FCGR2B (at least 3 exons) and the distal part of FCGR2C (two exons) is supported also by the presence of an additional copy (respectively three copies) for probes upstream of FCGR2B, and those for intron 2, exon 3 and intron 3 that detect the ORF allele from the wild-type FCGR2B gene (FCGR2B-wt) and the presence of 3 copies of probes that detect mutations in intron 7 of FCGR2C, respectively (fig. 2. Panel III).

TABLE I.
Patients' sample description

Patient	Age at diagnosis (years)	Gender	Platelet count at onset (/ml)	Bleeding severity (Buchanan grading)	Genetic mutations	Treatment	ITP outcome

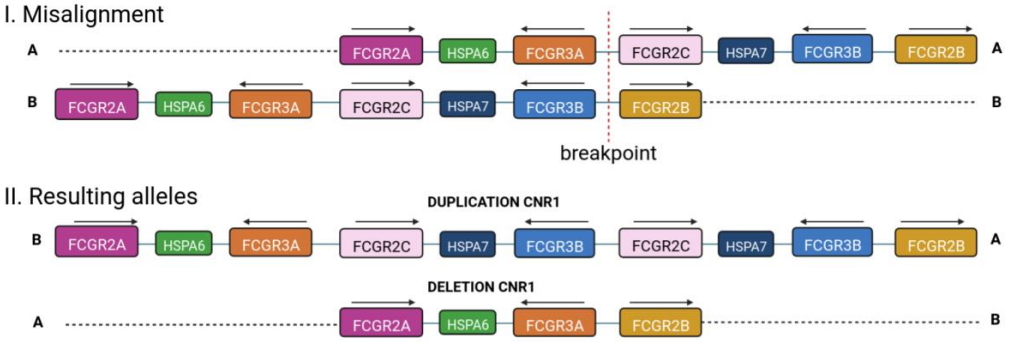

Fig. 1. Schematic representation of non-allelic homologous recombination (NAHR) creation of CNR1: Panel I: Misalignment of homologous chromosomes A and B. Red vertical lines indicate crossover breakpoints. Panel II: The resulting chromosomes, one with a CNR1 deletion and the other with a CNR1 duplication.

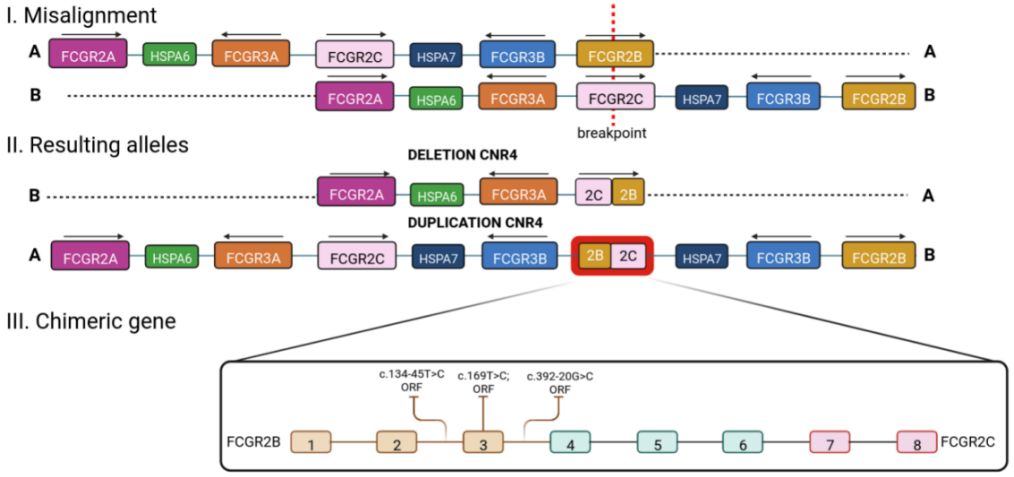

Fig. 2. Schematic representation of non-allelic homologous recombination (NAHR) creation of CNR4. Panel I: Misalignment of homologous chromosomes A and B due to an 82 kb repeat unit. Red vertical lines indicate crossover breakpoints. Panel II: The resulting chromosomes, one with a CNR4 deletion and the other with a CNR4 duplication.

Panel III: *FCGR2B* chimeric allele created by the fusion of the first three exons of the *FCGR2B* gene (in orange) and the last two exons of the *FCGR2C* gene (in pink); for exons 4 to 6 (in blue), there were no MLPA probes to specify their origin.

FCGR2C STOP/ORF haplotypes

To establish FCGR2C STOP/ORF haplotypes, 3 probes were evaluated for *FCGR2C*, in intron 2 (c.134-45T STOP), exon 3 (c.169T STOP) and intron 3 (c.392-20G STOP) respectively, in comparison with three nonspecific variants in the same positions for FCGR2B-wt or FCGR2C-ORF: c.134-45T>C ORF (intron 2), c.169T>C (exon 3), c.392- 20G>C ORF (intron 3) (fig. 3. Panel I). To obtain the

ORF/STOP copy number, we subtracted the *FCGR2B* gene copy number according to the genomic rearrangements previously determined using CNV-specific probes. We identified 9 patients with FCGR2C ORF haplotypes, 8 in heterozygous state and one in homozygous state (patient P12 with CNR4 duplication).

We further evaluated the four probes common for *FCGR2C* and *FCGR2A*-wt (fig. 3), in order to establish the classical or nonclassical ORF haplotypes: two probes located in the splicing site at the border between exon 7 and intron 7 (c.798+1A>G for classical ORF and c.798+1A presented in both nonclassical ORF 1 and ORF 2) and two probes in the splicing site at the border between intron 7 and exon 8 (c.799-1C>G ORF for classical ORF and nonclassical ORF1 and c.799-1C present only in nonclassical ORF2). Considering the number of copies of the *FCGR2A* gene we have determined the presence of classic and nonclassic ORF in *FCGR2C*. We set up the classic ORF in the *FCGR2C* gene in the presence c.798+1A>G and c.799-1C>G variants. In our study we identified 8 patients with classic ORF in heterozygous status.

The presence of c.798+1A with c.799-1C>G variant was considered nonclassical ORF1 and c.798+1A with c.799-1C was considered nonclassical ORF2. The nonclassical ORF1 was the most frequent haplotype identified in 14/16 patients, 6 cases in heterozygous status with classical ORF. Nonclassical ORF patients do not express FCGR2C.

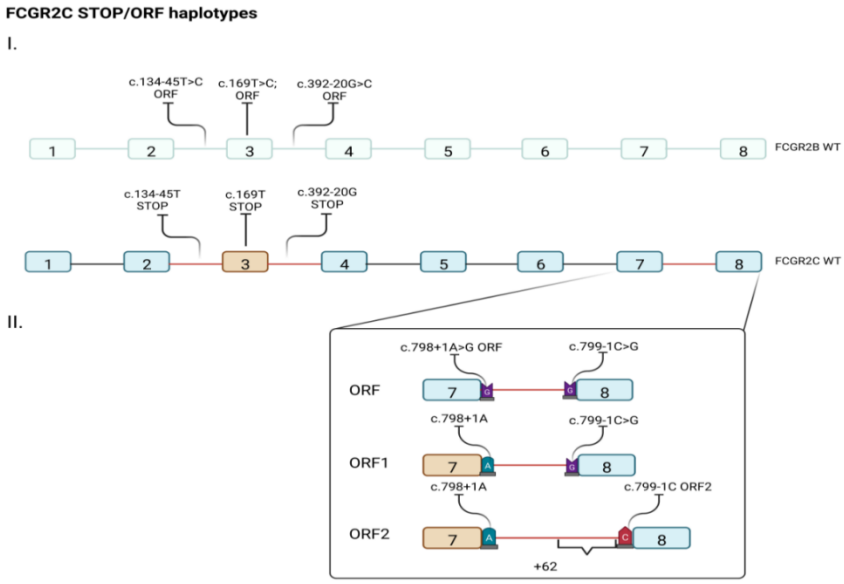

Fig. 3. Graphic representation of the FGCR2C STOP/ ORF haplotype. Panel I: Location of MLPA probes for ORF/STOP haplotype in FCGR2B and FCGR2C. Panel II: The position and combination of probes in classical and nonclassical ORF in FCGR2C gene

FCGR2B haplotypes

We identified the most frequent haplotype 2B.1 (9/16 patients) and the fewest haplotype 2B.4 in 3 patients, either in

combination with 2B.2 (2/16) or with 2B.2/2B.1 Furthermore, one of these patients had a CNR4 duplication.

FCGR3B haplotypes

The NA1, NA2 and SH haplotypes in *FCGR3B* are found in three polymorphic forms and determine the allotypic variants of the Human Neutrophil Antigen1 (HNA1). We constructed the haplotypes considering copy number variation using six probes in exon 3 in *FCGR3B* and *FCGR3A* gene (fig. 4). In our study we found two patients homozygous for NA1 (P1 and P3), three homozygous for NA2 (P7, P11, P14), the rest being heterozygous NA1/NA2, only one patient (P12) with CNR4 duplication was found heterozygous for NA1/NA2/SH.

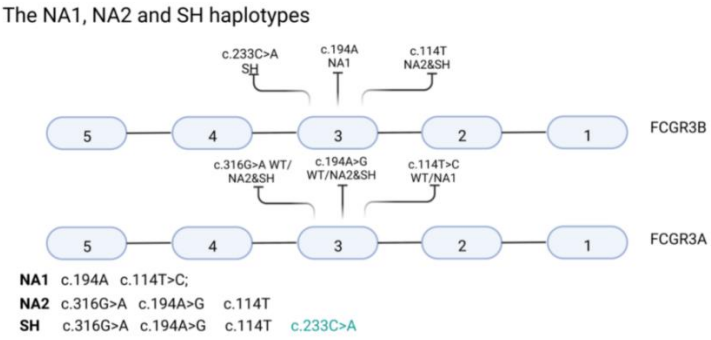

Fig. 4. Schematic representation of MLPA probes in *FCGR3B* and distinguishing between FCGR3B NA1/NA2/SH haplotypes.

Mutations

Several MLPA probes were designed to identify the mutations in FCGR2/3 locus. In our study we identified in FCGR2A gene, 9 patients with p.His166Arg, one patient in homozygous state (P15) and 5 patients heterozygous for p.Gln62Trp mutation.

The presence of valine at position 158 in protein FCGR3A (p.Val158Phe) was observed in 10 patients, two patients being in the homozygous state (P7 and P12, both with CNR4 duplication. Related to p.Ile232Tre mutation in the FCGR2B gene, we identified only 4 heterozygous patients.

Regardless the presence of mutations, these patients had a rather favorable evolution with good response to treatment (intravenous immunoglobulins and cortisone) and did not evolve to the chronic form. Thus, none of the genetic particularities of our patients correlated to the response to treatment or clinical outcome (tab. II)

DISCUSSION

Within the mechanism of ITP, FCGR determine effects on many levels, such as on antigen presentation, B-cell activation threshold, platelet clearance through FCGR on myeloid and/or natural killer (NK) cells, and it seems that the presence of certain polymorphisms influence response to different therapies. Fc receptors are glycoproteins that are found on different cells (neutrophils, macro-phages, lymphocytes, platelets) and are involved in creating connections between the humoral and cellular immune responses. The human FCGR family is represented by three major classes of receptors encompassing

12 transcripts derived from eight genes: FCGR1A, 1B and 1C; FCGR2A, 2B and 2C; FCGR3A and FCGR3B (10), all of which are present on chromosome 1. FCGRI is a high-affinity receptor for monomeric IgG, but the other receptors FCGR2 and FCGR3 need to form of immune complexes with IgG to express their function (low-affinity receptors). FCGR2 class is encoded by three genes (FCGR2A, 2B and 2C) and FCGR3 is encoded by two genes (FCGR3A and 3B).

The FCGR2 and FCGR3 genes show multiple genetic variants including functionally relevant SNPs and copy number variations (CNVs) that may influence antibody-mediated phagocytosis and antigen presentation activity.

These SNPs and CNVs have been associated with various autoimmune diseases (like systemic lupus erythematosus (SLE), multiple sclerosis, Addison disease, heparin-induced thrombocytopenia, PTI), infectious diseases, efficacy of immunotherapy and they have been shown to be involved in disease susceptibility (3, 10-12) and it is likely that other disease associations will be identified in the future.

After testing cohorts of patients using MLPA technique, it was possible to identify the CNRs present at this locus, now describing four distinct CNRs (13). Also, there were discovered chimeric genes at the locus and rearrangements resulted from the fusion of a part of either FCGR2A or FCGR2B to other parts of the locus (although their copy number is never increased or decreased). These modifications of genes have important consequences for expression and function (4, 13).

In our study we used the MLPA technique to identify the presence of FCGR2 and FCGR3 polymorphisms in patients diagnosed with immune thrombocytopenia.

The results of our study are marked by the limitations of a single-center study with a small number of patients, as a consequence of the rarity of the disease (0.2 – 0.4/100,000 inhabitants) and the inclusion of pediatric patients only. Therefore, we considered to provide a presentation of clinical evolution of our patients in relation with the particularities identified FCGR2/3 genes.

Various studies depicted the role of Human Fc Receptors in childhood immune thrombocytopenic purpura (tab. III).

FCGR2A is polymorphic and has two codominant expressed alleles, FCGR2A-H166 and FCGR2A-R166 (p.His166Arg). This polymorphic variation of FCGR2A results from a single base substitution at nucleotide position 497, (A or G) which codes for the amino acids histidine (H) or arginine (R), respectively, at position 166 and was formerly known as p.His131Arg. This amino acid substitution is associated with an important impaired ability of the receptor to bind human IgG2 (14). The allele H166 is the variant with a high affinity for human IgG2, whereas the other allele R166 arginine has a low affinity for human IgG2.

The gene for FCGR3A is mainly expressed on natural killer (NK) cells and monocytes. It has two polymorphic variant alleles due to a single base substitution of thymidine to guanine (T to G) at nucleotide 526 (c.526G>T). expressed in protein as p.Val158 (V158) and p.Val158Phe (F158) (13,15,16).

The FCGR3A-V158 variant (currently known as p.Val176Phe) has a higher affinity for IgG1 and IgG3 in comparison with FCGR3A-F158 (17). Inheritance of either higher or lower affinity FCGR variants may determine certain predispositions of individuals to FCG-dependent immune disorders (18-20).

Li *et al.*, conducted a meta-analysis of relevant studies to research the effects of FCGR polymorphism on susceptibility to ITP. FCGR2A H131R polymorphism was significantly associated with childhood-onset ITP, FCGR3A-158V polymorphism was significantly associated with both childhood-onset ITP and adult-onset ITP. Thus the authors proved that FCGR2A H131R polymorphism may serve as a potential genetic biomarker for childhood onset-ITP while FCGR3A-158V polymorphism for both childhood and adult-onset ITP (21).

The presence of variant FCGR3A V158 in ITP - was found by Amorim *et al.* (1) and Carcao *et al.* (22), but not by Papagianni *et al.* (23) Zakaria *et al.* (24), investigated the contribution of FCGR2A, and FCGR3A genes polymorphism to the risk of ITP and their association with disease characteristics in 80 patients and 80 controls. The combined His166/R166 and F158/V158 genotype was found be more prevalent in ITP patients compared with controls. The results showed no significant difference between frequency distribution of the FCGR2A and FCGR3A alleles and genotypes on children newly diagnoses ITP compared with chronic ITP (24).

In our study, 15/16 patients expressed FCGR2A-His166 variant. We found the heterozygous variant FCGR3A – V158/F158 (Val/Phe) in 8/16 patients; 2 patients with homozygous variant that present also CNR4 duplication. Our results are similar with the findings of Breunis *et al.* (2008) who analyzed the DNA from 116 patients with ITP and 100 controls and found that FCGR3A-V158/F158 are risk factor for childhood ITP, compared with FCGR3A-F158/F158 variant (25).

Breunis *et al.* found that FCGR2C-ORF is significantly associated with susceptibility to both adult and childhood ITP (25). Several molecular studies described FCGR2C-ORF (Stop/ORF/nc-ORF). In most people, the FCGR2C gene is not expressed due to a stop codon at c.169T in exon 3 (FCGR2C-p.Ter57). FCGR2C-ORF is scored in case of the presence of FCGR2C c.134-45T>C in intron 2, in exon 3 the FCGR2C c.169T>C (rs759550223) polymorphism converting the stop codon

into a glutamine and thereby enabling expression of the gene (FCGR2C-p.Ter57Gln) (8) and c.392-20G>C alteration in intron 3 (13).

The classic ORF haplotype consists of nucleotide changes in FCGR2C-ORF and absence of the intron 7 splice variant (c.798+1A; rs76277413). In the case of FCGR2C-ORF and c.798+1A, the haplotype was scored as FCGR2C-nc-ORF (nonclassic open reading frame).

In FCGR2C-nc-ORF1 and 2, presence of an A at the splice donor site c.798+1 result in splicing out of exon 7 and loss of expression due to a frameshift and activation of a novel stop codon in exon 8. In FCGR2C-nc-ORF 2, presence of C at 799-1 activates a cryptic acceptor splice site within intron 7 causing re-introduction of a 62 bp sequence of intron 7 into the transcript (fig.4, Panel II).

The MLPA technique cannot establish if two given mutations are on the same chromosome. As shown by Nagelkerke *et al.*, between FCGR2C-ORF variant in exon 3, c.169T>C, p.Ter57Gln (formerly known as p.57Q) and c.798+1G exist a very strong linkage disequilibrium, suggesting that these two variants are located on the same chromosome. If c.169T>C (p.Ter57Gln) is accompanied by c.798+1A the haplotype is designated "nonclassic" FCGR2C-ORF (9).

Taking this into account, we detected seven samples that were attributed to classical ORF haplotype (P2, P5, P7, P9, P12, P13, P14) and in which we appreciated that FCGR2C-ORF is expressed (tab. II). For patients P4 and P12, the alleles expressing the FCGR2C-ORF variant (p.Ter57Gln) are associated with the presence in intron 3 of the STOP variant (c.392-20G) and nonclassical ORF2 (in intron 7), which probably leads to low to absent expression of FCGR2C protein.

TABLE III.

Original studies depicting the role of Human Fc Receptors in childhood immune thrombocytopenic purpura

Study / Author	Study type and population	Aim	Results
Schmidt *et al.*, 2019 (26)	Randomized controlled trial (TIKI study) 180 children with newly diagnosed with ITP, aged 3 months - 16 years and 180 healthy controls.	To evaluate whether the known FCGR 2/3 polymorphism are a risk factor for ITP, and to what extent it is related to clinical outcome and response to IVIg.	The variant FCGR2C-ORF and FCGR2A- p Gln62Trp allele were overrepresented. The FCGR2C-ORF and FCGR2A- p. Gln62Trp are associated with a transient I course of ITP and a favourable response to IVIg. A combined deletion of FCGR2C/FCGR3B (CNR 1 deletion) was associated with prolonged disease courses and nonresponse to IVIg.
Papagianni *et al.*, 2013 (23)	Prospective multicentre study 53 children aged 6 months old- 15 years with newly diagnosed and chronic ITP and 45 controls.	To assess the link between FCGR polymorphism and therapeutic response to IVIg.	No significantly difference between allelic frequencies FCGR2A, FCGR3A in children with ITP compared with healthy controls. No association between the two FCG receptors and the therapeutic response to IVIG. The genotype FCGR2A - 158VF had a significant higher frequency in children with ITP

Foster *et al.*, 2001 (15)	Prospective study 37 Caucasian children with chronic ITP and 218 healthy controls	To investigate the distribution of common polymorphisms in 11 candidate genes. This included three structural variants in low affinity FCGRs: FCGR2A, FCGR3A, FCGR3B.	Strong association with ITP was noticed in FCGR3A, FCGR3B, TNF and LTA. 81% of patients with chronic ITP possessed one or both higher risk variant genotypes: FCGR3A V/F or FCGR3B NA1/NA1
Heitink-Pollé *et al.*, 2018 (27)	Prospective, multicentre, stratified open, parallel group study on 200 children aged 3 months -16 years.	To investigate whether IVIg treatment decrease the risk of chronicity in ITP. Among baseline characteristics of the study samples, genetic variations in FcgR genes FCGR2A, FCGR2B, FCGR2C, FCGR3A, and FCGR3B, was sought.	The patients with genotype FCGR2B – 232I responded to IVIg. The homozygous FCGR2B-232T patients did not respond.
Amorim *et al.*, 2012 (1)	Prospective study 39 subjects' children with acute and chronic ITP, aged 1-10 years and 78 children – control group.	To investigate the receptor gene polymorphism in children with ITP	An association of the polymorphic allele FCGR3A with ITP was found.
Carcao *et al.*, 2003 (22)	Retrospective study 98 children, aged 6 months old – 16 years, with acute and chronic ITP, and 130 healthy adult controls	To report the occurrence of polymorphic genotypes FCGR2A and FCGR3A childhood ITP.	An over-representation of the homozygous FccRIIa-131H/H genotype in ITP children *vs.* control group was found.
Bruin *et al.*, 2004 (2)	Prospective study 60 children, aged 6 mo-16 years newly diagnosed with ITP.	To investigate which patient variables, including FGR2B-232I/T predict the development towards chronic ITP.	Female gender was 3 times higher more susceptible to develop chronic ITP. Lack of infection at onset correlate with a 3.6 higher possibility for chronicity. The presence of genotype FCGR2B-232I/T had a six times higher risk for chronicity compared with FCGR2B- 232I/I.
Zakaria *et al.*, 2023 (24)	Case control study 80 children with primary ITP and 80 healthy controls	To investigate the contribution of FcyRIIa and FcyRIIIa genes polymorphism to the risk of ITP and their association with disease characteristics in Egyptian children	A significant difference genotype distribution and allelic frequencies for FcyRIIa, and FcyRIIIa polymorphism in ITP patients versus controls ($p < 0,05$) was found.

The nonclassical ORF1 was the most frequent haplotype identified in 14/16 patients, 6 cases in heterozygous status with classical ORF. Nonclassical ORF patients do not express FCGR2C.

Concerning ITP susceptibility, Caucasian Europeans seem to express an important disequilibrium among FCGR2A-

p.Gln62Trp, FCGR2C-ORF, FCGR3A-V158, and the 2B.4 promoter (4, 13, 16). Classical FCGR2C-ORF and 2B.4 seem to be correlated with the transient forms of ITP and a good response to IVIg (26).

We establish the haplotypes for *FCGR2B* and *FCGR2C* promoters as follows: the 2B.4 haplotype is considered in the presence of -386C/-120A and was assigned only to the *FCGR2B* as previous studies demonstrated (2); haplotype 2B.1 is considered in the presence of -386G/-120T and haplotype 2B.2 in the presence of -386C/-120T and was assigned to the *FCGR2C* gene. Only 3 of our patients present associated haplotype 2B.4 and classical FGCR2C-ORF (P2, P12, P13) and had the acute form of the disease and good response to IVIg, even though there are not significant differences between their clinical presentation and the other patients from the study group.

In the study performed by Schmidt *et al.*, probably the largest one in children with ITP (TIKI trial), the presence of FCGR2A – p.Gln62Trp allele significantly associated with transient ITP and a good response to IVIg. Also, the variant FCGR2C-ORF and FCGR2A- p.Gln62Trp allele were overrepresented (26). In our study 5 patients were heterozygous for FCGR2C-p.Gln62Trp (patients P2, P5, P12, P14, P16), all of them presenting a short course of disease, good response to cortisone and IVIg and no relapses. Also, the CNR1 deletion was found significant for the susceptibility of developing the chronic form of the disease and with a lower response to IVIg (26). As opposed to this, our patient that we found with the CNR1 deletion, responded well both to cortisone and IVIg, had a few relapses, but did not develop chronic ITP.

In Bruin's study (2) over 60 children with newly diagnosed ITP, the presence of heterozygote FCGR2B- p.Ile232Tre mutation (Ile232/Tre232) increased six times the risk of developing chronic ITP comparing with the genotype FCGR2B – p.Ile232 the homozygous state (Ile232/Ile232) (2). In our sample, we identified only 4 heterozygous patients (P8, P10, P11, P14) with the mutation Ile232/Tre232 in the FCGR2B gene, but unlike Bruin's study, their outcome was very good, with a positive response to corticosteroids and no relapses.

Apart from the risk of chronicity, Heitink-Pollé *et al.* (28) indicated that patients with homozygous FCGR2B-Tre232/Tre232 did not respond to IVIg treatment while all complete responders presented FCGR2B –Ile232 allele (27). Neither of the patients in our study group presented FCGR2B- Tre232/Tre232 variant which could be consistent with their good clinical evolution.

Nagelkerke *et al.*, investigated the genetic variation in the FCGR2/3 locus in auto-immune and auto-inflammatory disease, and how the FcyR variants relate to treatment response and outcome. FCG2B - p.232Thr allele expression is increased in adult ITP and in chronic childhood ITP. In adult autoimmune diseases there is an association of classic FCGR2C-ORF with ITP, while in childhood autoimmune diseases, classic FCGR2C-ORF confers susceptibility to childhood ITP as well as Kawasaki disease. Classic FCGR2c-ORF and 2B.4 correlate positively with the response to intravenous immunoglobulins in childhood ITP. Moreover, these variants are associated with transient disease course, and not to chronic thrombocytopenia (28).

Other candidate gene polymorphisms have been studied by Foster *et al.* (2001) in

a cohort of children with chronic ITP. The genes include three structural variants in low-affinity FCGRs (FCGR2A, FCGR3A and FCGR3B) and regulatory variants in eight cytokine genes (TNF, LTA, IL1A, IL1B, IL1RN, IL4, IL6 and IL10). A strong association with ITP was observed in four loci (FCGR3A, FCGR3B, TNF and LTA). The heterozygous V158/F158 genotype of FCGR3A was increased in chronic ITP patients compared with controls (62% vs 41%). 81% of children with chronic ITP possessed one of both of the higher risk variant genotypes of FCGR3A V158/F158 and FCGR3B NA1/NA1) *versus* 50% of controls (15).

Furthermore, it has been demonstrated an association between FCGR genotypes characterized by increased immunoglobulin binding activity (FCGR3A allele V158 and FGCGR3B allele NA1) and chronic children ITP (15). In our study, only 2/16 patients express NA1 in homozygous state, one having V158/F158 (P1) and one F158/F158 (P3). The first patient that associated also CNR1 deletion presented persistent ITP, while the other responded well to the treatment and did not relapse.

In our sample, three patients were homozygous for NA2, the rest (12 patients) being heterozygous NA1/NA2 and only one patient, which presents CNR4 duplication was found heterozygous for NA1/NA2/SH. This patient had a good response to IVIg and did not have any relapses.

CONCLUSIONS

Several studies showed the genetic involvement of the FCGR2/3 locus presenting many functional genetic variants in complex linkage (13, 16, 26). A variety of other illnesses (e.g., Kawasaki disease), also linked to this polymorphism, could further provide us with important information about fundamental variations in pathophysiologic mechanisms (13). The locus is also promising in terms of genetic therapeutic efficacy prediction, particularly for cancer immunotherapy, even though this is not yet applicable. A complete genetic analysis could be helpful for research on the locus, given its intricacy and errors in the current databases containing reference sequences. This kind of technique has recently been investigated for FCGR3A employing long-range sequencing with Oxford Nanopore technology, allowing a thorough analysis of polymorphism locations within the gene (29).

The best course of treatment for ITP in children needs to consider medical factors such as platelet count, FCG polymorphism, clinical history, bleeding severity but also the moral values such as beneficence, non-maleficence, and respect for parents/patient' autonomy. Further research on ITP in children, particularly focused on genetic interference with disease outcome are needed. However, this research on a potentially vulnerable population like this needs to be conducted in a safe and respectful of the child's rights and welfare, such as obtaining informed consent from the child and their parents or guardians, minimizing potential harms, and ensuring confidentiality (30). A thorough analysis of all SNPs and CNVs together is required to take full use of genetic diversity at the FCGR2/3 locus. The MLPA analysis is useful to give an overview of the genetic alterations of this locus as it is shown in our study. Our findings were overall concordant with other studies' results except for the CNR4 duplication, which would need to be studied in a larger lot of patients to establish

whether it is connected to the predisposition to develop ITP.

With this study we aimed to evaluate the genetic risk factors in the FCGR2/3 locus that were identified in childhood ITP. All the variations detected in our patient group were associated with limited course of the disease and good response to IVIg. These findings could suggest a specific population particularity. The results must be interpreted with caution due to the small sample and confirmation in a larger prospectively recruited cohort of children with ITP is needed.

EXPLORING THE RELATIONSHIP BETWEEN PSYCHOSOCIAL RISKS, BURNOUT LEVELS, AND EMOTIONAL INTELLIGENCE AMONG MEDICAL AND NON-MEDICAL PERSONNEL IN ROMANIAN MEDICAL UNITS. (Abstract). Emotional intelligence implies the ability to perceive, understand, manage, and express emotions effectively, both in oneself and in others. Burnout is a state of emotional, physical, and mental exhaustion caused by prolonged and excessive stress, particularly related to one's job or work environment. Psychosocial risks at work refer to factors in the work environment that can influence employees' psychological and social well-being. **The objective** of this study was to investigate the differences between medical and non-medical personnel regarding burnout, emotional intelligence, and perceived psychosocial risks at work in healthcare facilities in Romania. **Material and methods**: A cross-sectional study was conducted in February-March 2023 on a sample of 500 healthcare specialists, including 217 nurses, 98 physicians, and 55 respondents with other medical specialities (e.g., psychologists, biologists, pharmacists, physiotherapists etc.), along with 130 non-medical personnel from public and private healthcare units in Romania. Data was collected using the Maslach Burnout Inventory (MBI HSS), UNIPSICO Battery, Trait Meta-Mood Scale (TMMS-24), and Eco System. **Results:** For medical personnel, burnout scores were as follows: emotional exhaustion (M = 19.73 ± 13.68), depersonalization (M = 4.44 ± 4.99), and personal accomplishment (M = 38.67 ± 7.45). Non-medical personnel showed higher values in emotional exhaustion (M = 27.33 ± 14.16), depersonalization (M = 6.59 ± 5.99), but lower scores in personal accomplishment (M = 35.87 ± 7.92). Organizational justice scores were lower for non-medical personnel (M = 21.63 ± 5.61) compared to medical personnel (M = 25.87 ± 5.86). Regarding protective factors against burnout, in terms of emotional intelligence, emotional attention had values of (M = 30.30 ± 5.87) for medical personnel and (M = 31.63 ± 5.05) for non-medical personnel. For emotional clarity, medical personnel scored (M = 31.34 ± 4.96) and non-medical personnel scored (M = 31.93 ± 4.59), while for emotional repair, medical personnel scored (M = 29.97 ± 4.28) and non-medical personnel scored (M = 29.68 ± 4.30). Role conflict showed higher scores for non-medical personnel (M = 9.61 ± 4.34) compared to medical personnel (M = 7.25 ± 4.27). Role clarity scores were higher for medical personnel (M = 16.25 ± 3.61) and lower for non-medical personnel (M = 16.06 ± 3.51). Workload scores were higher for non-medical personnel (M = 24.19 ± 8.02) and lower for medical personnel (M = 21.97 ± 7.90). **Conclusions:** Medical personnel experiences a higher sense of organizational justice and personal accomplishment compared to the non-medical staff. In the case of the neg-

ative dimensions of burnout, higher levels of emotional exhaustion and depersonalization have been recorded among non-medical personnel. Additionally, for emotional attention dimension, higher scores have been registered among the non-medical staff. Regarding other psychosocial risks, role conflict has recorded higher values among administrative personnel, as well as workload. **Keywords:** MEDICAL PERSONNEL, NON-MEDICAL PERSONNEL, BURNOUT, EMOTIONAL INTELLIGENCE, ORGANIZATIONAL JUSTICE, PSYCHOSOCIAL RISKS.

Burnout is a psychological response that occurs when individuals experience prolonged exposure to stress (1). The concept of burnout was first introduced by Herbert Freudenberger in the early 1970s and 1980s, who noticed that exhausted colleagues showed a lack of motivation at work. He described burnout as a feeling of exhaustion resulting from striving excessively to meet idealistic expectations. He believed burnout could stem from unmet self-imposed or socially influenced expectations, leading to physical and emotional exhaustion. This state can cause individuals to feel ineffective, drained, and detached from their work, thus hampering productivity and success (2).

The European Agency for Safety and Health at Work categorizes psychosocial risks into factors like excessive workload, conflicting demands, and uncertainty about the worker's role and responsibilities (3). *Role conflict*, also known as role-related conflict, refers to a scenario where a worker finds it challenging to meet conflicting role expectations simultaneously. It occurs when an individual receives contradictory demands or responsibilities from multiple sources, making it difficult to reconcile these conflicting roles. Another aspect of role conflict is when a worker faces tasks that require resources they lack, hindering their ability to fulfil the assigned duties adequately. Role clarity refers to the extent to which there is a lack of clear information or clarity regarding the expectations associated with a particular role (4). Numerous studies have demonstrated a positive correlation between role clarity and burnout (5). *Emotional intelligence* was introduced to the psychology literature in the 20th century by Salovey and Mayer in 1990. Mayer and Salovey define emotional intelligence as the ability to recognize, understand, and regulate one's own emotions and the emotions of others, to differentiate between them, and to use this information to guide thoughts and actions (6). In 1995, Daniel Goleman wrote the best-selling book "Emotional Intelligence" which popularized the concept of emotional intelligence worldwide (7). Emotional intelligence acts as a protective factor against the impact of psychosocial factors. According to the model of the four branches of emotional intelligence, having appropriate intrapersonal and interpersonal qualities predicts better emotion regulation and effective emotional management. Perceiving emotions involves acknowledging and recognizing emotional information, while using emotions requires activating rational thinking. Understanding and analysing emotions involves cognitive processing, from labelling emotions to distinguishing between words and actual emotions. Lastly, managing emotions reflects the ability to handle one's own emotions and the emotions of others (8).

Healthcare specialists, including nurses, doctors, pharmacists, physiotherapists, biologists, psychologists, and social work-

ers, face challenging tasks, heightened difficulty, significant responsibility, and a strong sense of dedication (9). The primary psychosocial hazards encountered by personnel in the healthcare sector are related to workload, organizational justice issues, emotional regulation, conflicting demands, and role conflicts (10).

Healthcare professionals also include the administrative staff of a general hospital, who play a crucial role in providing and processing various data necessary for managerial decision-making. They efficiently manage the workforce, facilities, and budgets while coordinating and handling conflicting interests among different departments, such as medical treatment, healthcare, and support services departments (11). Healthcare professionals face daily challenges at work, including psychosocial factors that can make their job demanding. These psychosocial risks have been associated with burnout (12). The impact of psychosocial risks can influence both psychological and physical health through psychophysiological mechanisms triggered by stress. An overload of demands and emotional requirements, coupled with inadequate personal or material resources to cope with them, can lead to this adverse psychological state in workers (13).

Despite the significant relevance of psychosocial risks and emotional intelligence in influencing burnout, there is a notable scarcity of research focusing both medical and non-medical personnel in healthcare units. After conducting a thorough review of existing literature, no studies were found that specifically investigated the psychosocial risks faced by both categories of personnel mentioned earlier and their association with emotional intelligence, considering burnout.

Hence, the present study aims to bridge this gap in the literature by conducting an analysis of the impact of psychosocial risks and emotional intelligence on burnout levels for medical and non-medical personnel among Romanian healthcare specialists.

MATERIAL AND METHODS

Participants and data collection

Between February and March 2023, a cross-sectional study was conducted using the snowball sampling method. An online questionnaire was developed and distributed through Google Forms. The distribution of the questionnaire was facilitated by the Order of General Medical Assistants, Midwives, and Medical Assistants in Romania, as well as the heads of departments from public and private medical facilities located in Iasi, Constanta, Oradea, Cluj, Bucharest, and Timis. Additionally, the questionnaire was made available through the Pharmacists' College in Romania, the College of Psychologists in Constanta, the Association of Legal Advisors from Public Hospitals, the Association of Quality Management Officers in Public Hospitals, and the Sanitas Constanta Trade Union.

The group of participants in the study comprised 370 medical staff respondents, including doctors, nurses, physical therapists, biologists, pharmacists, psychologists, social workers, and others. Additionally, there were 130 non-medical (administrative) staff respondents who were employed in hospitals and health facilities across Romania. So, a total of 500 subjects were included in the research. The participants worked in various types of hospitals, including municipal, clinical, regional, county, or polyclinic hospitals, in both the private and public sectors.

To be eligible for inclusion in the

study, participants had to be currently employed in Romanian hospitals, clinics, or state/private institutions. Any participants who submitted their answers after the specified deadline were excluded from the analysis.

In the study, the respondents were categorized into two groups based on their professions, to gain insights into sector-specific challenges. Medical and non-medical personnel often encounter distinct challenges within their respective fields, and identifying sector-specific factors contributing to burnout was a primary aim. Moreover, there is a lack of research comparing these different categories of personnel, with non-medical staff being particularly underrepresented in healthcare studies, especially in Romania. By analyzing both medical and non-medical personnel, the study offers an opportunity to compare their experiences. This comparative analysis helped shed light on the differences in symptoms and the impact of burnout across different fields. Previous research has indicated that non-medical personnel may face higher levels of workload, emotional exhaustion, and depersonalization, as well as lower scores for personal accomplishment (14). Moreover, another study analysing in comparison Romanian medical and non-medical personnel illustrated that wellbeing and organizational justice, are higher also for medical personal (15).

Instruments

Burnout—The 22-item Maslach MBI Human Services Survey (MBI-HSS) measuring instrument (16) was used to measure the level of burnout. MBI-HSS is the original and most widely used variant of the tool. The instrument contains 22 items, to which participants are asked to respond on a Likert scale from 0 to 6, where 0 = never and 6 = always. The instrument contains three dimensions: emotional exhaustion, depersonalization, and personal accomplishment. Examples of scale items are *I feel emotionally drained from my work* (emotional exhaustion); *I feel very energetic* (personal accomplishment); and I'*ve become more callous towards people since I took this job* (depersonalization). High scores for the emotional exhaustion and depersonalization dimensions and low scores for personal accomplishment correspond to higher levels of burnout (17). In the research sample, the Cronbach Alpha consistency coefficients for each subscale range from acceptable to excellent, namely $\alpha = .94$ (emotional exhaustion), $\alpha = .79$ (personal accomplishment), and $\alpha = .70$ (depersonalization).

The Trait Meta-Mood Scale (TMMS-24) was used to evaluate emotional intelligence (18). It is a shorter version of the TMMS-48 (19), containing 24 items that are categorized into three dimensions: attention, clarity, and repair. Participants responded to the items using a five-point Likert scale, ranging from 1 (strongly disagree) to 5 (strongly agree). Examples of the items include: "I pay a lot of attention to my feelings" (attention), "My feelings are clear to me" (clarity), and "Even when I feel sad, I try to think about pleasant things" (repair). Psychometric properties of this instrument were found to be good in previous studies (all Cronbach's alphas > 0.85) (18) In our study, attention $\alpha = .91$, clarity $\alpha = .91$, repair $\alpha = .78$.

The UNIPSICO Battery (Unidad de Investigación Psicosocial de La Conducta Organizacional) (20) was used to evaluate psychosocial risks. This battery assesses the psychosocial risks faced by workers, considering three key factors: demands, resources, and consequences. Participants

provided responses to all items using a five-point Likert scale, ranging from 0 (never) to 4 (very often: every day). Previous studies have demonstrated that this instrument possesses good psychometric properties (Cronbach's alphas > 0.86) (20). Specifically, the scales of the UNIPSICO Battery utilized in this research were:

The Role Conflict Scale measures the instances where an individual faces challenges in satisfying conflicting role expectations that they are involved in. It serves to assess psychosocial demands. The scale includes five items, with example statements such as "I receive incompatible requests from two or more people." The internal consistency of the scale for this study's sample was determined to be Cronbach's alpha = .85.

The Role Clarity Scale was assessed using the UNIPSICO subscale (20). This subscale consists of 5 items with a Cronbach's alpha of .82. The items pertain to aspects like knowledge of job attributions and competencies, objectives, tasks, responsibilities, and job content, as well as understanding how to perform the job and the worker's expected role (e.g., "I know exactly what is expected of me at work").

ECO system (21) was used for measuring organizational justice via the dimension of organizational justice (8 items) to measure the psychosocial risks at the organizational level. It was measured on a 5-point Likert scale, where 1 = to a very small extent and 5 = to a very large extent. An example of items is "The salary I receive is correct relative to the work I am doing". The scale was used in organizations in Romania in the past; it has its own specificity, where employees are under the influence of similar professional pressures and working conditions but hold different positions in an organization, as in our study (medical and non-medical staff). On the research sample, an acceptable internal consistency coefficient is found for the organizational justice sub-scale, $\alpha = .74$. The ECO system was also used to measure workload - with the dimension Workload (8 items) to measure psychosocial risks at the organizational level. The dimension of workload presented adequate psychometric properties in previous studies (Cronbach's alphas > 0.78) and organizational justice (Cronbach's alphas > 0.81), (22) and the present one. On the research sample, a very good internal consistency coefficient was found for the workload sub-scale, $\alpha = .90$.

Statistical analyses. The *IBM Statistical Package for Social Sciences* (SPSS) and Statistics for Windows, *version 29* (SPSS Inc., Chicago, IL, USA) were used to test the hypotheses. The first group included medical personnel (doctor, nurse, physical therapist, psychologist, pharmacist, biologist, chemist, and social worker), and the second one included non-medical personnel (administrative staff).

Ethical approval. The study was conducted in accordance with the Declaration of Helsinki and approved by the Institutional Board of the Association of Legal Advisors from Public Hospitals in Romania, Research Ethical Agreement No. 54/15, September 2022.

RESULTS

Socio-Demographic and Job-Related Data

The study included 370 medical staff respondents and 130 administrative staff respondents. Table I presents the demographic data. Most of the participants were female (85.2%). About 80.20% of the participants were in a relationship, 75.80%

had children, and 41.80% had more than 20 years of work experience. Additionally, 72.40% of the respondents worked in a public institution, and 35.00% worked in an emergency unit. Moreover, 24.40% held a management position, 37.40% had a bachelor's degree, and 29.60% reported suffering from chronic diseases.

TABLE I.
Characteristics of the study sample (n = 500)

Characteristics	N	%
Gender		
Male	74	14.80%
Female	426	85.20%
Marital status		
Single	99	19.80%

Descriptive statistics

The data was entered into SPSS version 29 for hypothesis testing and statistical analysis. The research sample consisted of 426 women (85.2%) and 74 men (14.8%). Among them, 98 were physicians (19.6%), 217 were nurses (43.4%), 130 are administrative staff (26%), and 55 (11%) belonged to other professions (such as physiotherapists, psychologists, pharmacists, biologists etc.).

Inferential Data Analysis

H1: There are statistically significant differences in psychosocial risks, burnout, and emotional intelligence between medical and non-medical staff.

To investigate this hypothesis, an independent samples T-test was applied. The results indicate that there were signif-

icant differences between the two groups concerning emotional exhaustion, professional accomplishment, depersonalization, organizational justice, emotional attention, role conflict, and workload (tab. III).

TABLE III.
T test for independent sample

	Medical		Non-medical		t	Cohen's d
	M	SE	M	SE		
Emotional exhaustion	19.73	0.71	27.33	1.24	-5.39**	-0.55
Personal accomplishment	38.67	0.39	35.87	0.69	3.63**	0.37
Depersonalization	4.44	0.26	6.59	0.52	-3.99**	-0.40

Nmedical = 370; Nnon = 130; *p < .05; **p< .001

H2: Psychosocial risks (organizational justice, role conflict, workload, and role clarity) have a statistically significant correlation with burnout.

According to the correlation analysis (Table 2), it can be observed that the dimensions of burnout correlate with different psychosocial risks for both professional domains. For the medical staff, statistically significant correlations were found between the dimensions of emotional exhaustion and organizational justice ($r = -.45$, $p < .01$), role conflict ($r = .52$, $p < .01$), workload ($r = .5776$, $p < .01$), and role clarity ($r = -.39$, $p < .01$). The second dimension, personal accomplishment, correlates significantly and positively with organizational justice ($r = .26$, $p < .01$) and role clarity ($r = .48$, $p < .01$), and negatively with role conflict ($r = -.22$, $p < .01$) and workload ($r = -.25$, $p < .01$). On the other hand, depersonalization correlates negatively with organizational justice ($r = -.31$, $p < .01$) and role clarity ($r = -.40$, $p < .01$), and positively with role conflict ($r = .41$, $p < .01$) and workload ($r = .29$, $p < .01$).

Similarly, for the non-medical staff, significant correlations were observed between emotional exhaustion and organizational justice ($r = -.28$, $p < .01$), role conflict ($r = .45$, $p < .01$), and role clarity ($r = -.19$, $p < .01$). Regarding personal accomplishment, there was a significant correlation only with role clarity ($r = .29$, $p < .01$). The last dimension, depersonalization, correlates negatively with organizational justice ($r = -.24$, $p < .01$) and role clarity ($r = -.23$, $p < .01$), and positively with role conflict ($r = .41$, $p < .01$).

H3: Emotional intelligence will positively correlate with the dimension of personal accomplishment and negatively cor-

relate with the dimensions of emotional exhaustion and depersonalization.

The correlation coefficients indicate that personal accomplishment significantly and positively correlates with all three dimensions of emotional intelligence (emotional attention, emotional clarity, and emotional repair) for both groups. However, in the case of medical personnel, stronger correlations (medium or large effect sizes) were observed with clarity ($r = .42$, $p < .01$) and emotional repair ($r = .41$, $p < .01$) compared to non-medical personnel, who showed smaller or medium correlations with these dimensions of emotional intelligence.

Regarding emotional exhaustion, significant and negative correlations were observed only for healthcare personnel, with clarity ($r = -.22$, $p < .01$) and emotional repair ($r = -.24$, $p < .01$). For non-medical personnel, there were no significant correlations. Similarly, depersonalization presented significant and negative correlations only for healthcare personnel, with all relationships being negative.

Thus, the dimensions of burnout were closely related to the dimensions of emotional intelligence, but only for healthcare personnel. For non-medical personnel, only personal accomplishment was affected by emotional intelligence.

DISCUSSION

Regarding burnout, non-medical personnel face higher values for emotional exhaustion as well as depersonalization than medical personnel, and higher values for personal accomplishment for medical personnel. Scholars in the field have reached an agreement that burnout tends to manifest gradually rather than showing immediate symptoms. It develops as a response to emotional exhaustion and prolonged exposure to stressors. As individuals experience emotional exhaustion and face continuous stressors, this can contribute to an acceleration in the degree of dehumanization and a sense of dissatisfaction with their professional roles (23, 24). The administrative personnel seem to undergo increased emotional exhaustion and depersonalization, leading to symptoms like weariness, diminished motivation, and a cynical attitude towards colleagues or stakeholders. These adverse consequences may be intensified by heavy workloads, scarce resources, and stress in the workplace (15). Emotional exhaustion and depersonalization results for administrative personnel may be caused by a lack of control because this category of stuff may have limited decision-making power in critical situations, leading to feelings of vulnerability and frustration. At the same time, administrative personnel might feel undervalued or underappreciated for their contributions to patient care, leading to a sense of depersonalization and disengagement, known as a lack of recognition.

Regarding psychosocial risks, administrative staff face higher levels of workload and lower levels of organizational justice. Concerning workload and resource disparities: non-medical staff may face heavier workloads and fewer resources than medical personnel, leading to higher stress levels and reduced job satisfaction. Based on previous studies, it has been observed that non-medical staff often perceive a lower level of organizational justice. This perceived injustice might be attributed to salary disparities between the two categories of staff in healthcare in Romania (14).

Role conflict is also higher for non-medical personnel. Role conflict has

emerged as a significant predictor of burnout. In previous research, it was revealed that behind this evidence is the fact that the levels of the burnout syndrome are significantly and positively correlated with role conflict. The relationship between role conflict and burnout suggests that as role conflict increases, so does the likelihood of experiencing burnout (4). The lack of organizational justice can also cause emotional exhaustion (25). In the case of emotional intelligence, the protective factor of burnout, significant differences between the two subgroups with higher values for administrative stuff were registered only for emotional attention. Hence, one reason could be team dynamics since administrative personnel might need to coordinate and cooperate with various healthcare teams and departments. Higher emotional attention could facilitate better teamwork, communication, and conflict resolution, which are essential for effective healthcare administration. Another reason could be represented by job stressors: while medical personnel face stress linked to patient care and medical decisions, administrative personnel may experience stress from managing administrative tasks, handling complex logistics, and coordinating multiple tasks. Higher emotional attention might help them manage and cope with these stressors successfully.

For the medical staff, statistically significant correlations were found between the dimensions of emotional exhaustion and organizational justice, role conflict, workload, and role clarity. In the case of non-medical staff, significant correlations were observed between emotional exhaustion and organizational justice, role conflict, and role clarity. Regarding the correlation between burnout and psychosocial risks, in the case of emotional exhaustion, a negative correlation was found with organizational justice, suggesting that employees who perceive fairness and equity in the organization are less likely to experience emotional exhaustion. When they believe that they are treated fairly, this can act as a barrier against burnout. Physicians who face a heavy workload and extended working hours are at higher risk of experiencing burnout (26).

Additionally, role conflicts and emotionally demanding jobs further contribute to feelings of emotional exhaustion and depersonalization. In previous studies, emotional exhaustion showed a significant and strong positive correlation with workload as well as with role conflict (27).

In case of medical personnel, emotional exhaustion is also positively corelated with workload which means that a higher workload may lead to increased emotional exhaustion as it can be physically and emotionally draining for medical staff to handle a heavy workload. Experiencing a heavy workload, increased work intensity, and irregular work schedules leads to a lack of concentration, memory issues, and hinders the ability to think clearly and make decisions. When employees perceive the need to handle multiple tasks simultaneously and be innovative, it can result in sleep disturbances and contribute to burnout. Furthermore, the presence of high emotional demands in the workplace, including dealing with emotionally challenging situations and personal problems of others, along with the need to maintain emotional coherence with work, can also lead to sleep disturbances, stress, and somatic problems (28).

The negative correlation of both groups with emotional exhaustion and role clarity could mean that clear and well-defined

roles and duties may mitigate emotional exhaustion as they reduce ambiguity and uncertainty. The research found a statistically significant correlation between emotional exhaustion and role conflict. This means that medical and non-medical personnel staff members who experience higher levels of role conflict (e.g., managing multiple tasks, conflicting burdens etc.) are more likely to experience emotional exhaustion. The demanding and high-pressure nature of medical professions can contribute to this phenomenon. Clarity about their tasks and responsibilities may help non-medical staff handle their work more effectively, leading to lower levels of pressure and emotional exhaustion.

In the case of medical personnel, the second dimension, personal accomplishment, correlates significantly and positively with organizational justice and role clarity and negatively with role conflict and workload. Results are consistent with previous studies, where role conflicts had a positive correlation with burnout in the case of nurses and may contribute to higher levels of burnout registered for this category of employees (29).

In the case of administrative staff, personal accomplishment corelates only with role clarity. In the case of medical personnel, there is also a positive correlation with organizational justice: when employees feel that they are rewarded fairly and recognized for their achievements, it enhances their sense of personal accomplishment. The positive correlation of personal accomplishment with role clarity means that clearly defined roles allow medical and non-medical staff to better understand their responsibilities and contribute to a sense of accomplishment when performing their roles successfully. The negative correlation of personal accomplishment with role conflict for medical personnel suggests that an environment where healthcare professionals experience conflicting tasks or expectations could affect the sense of personal accomplishment felt by them (28). As expected, another negative correlation was established between personal accomplishment and workload in the case of medical personnel because high overload can negatively impact the feeling of personal accomplishment, as it may be difficult to achieve a sense of success when overwhelmed with tasks.

The third dimension of burnout, depersonalization, correlates negatively with organizational justice for both subgroups: when employees feel that they are treated unfairly, they might respond by developing a sense of detachment toward their work and patients.

The negative correlation between depersonalization and role clarity for the two groups could lead to misunderstandings and a sense of detachment from one's tasks, potentially contributing to depersonalization. The lack of role clarity is a psychosocial risk factor that significantly impacts workers' well-being and performance levels. When employees are uncertain about their roles and responsibilities, they tend to invest less effort in their tasks and perform less effectively. Consequently, these workers show reduced engagement and, as a result, experience lower levels of well-being and job satisfaction. Studies have demonstrated that the presence of unclear goals is associated with diminished performance, job satisfaction, and overall engagement among healthcare professionals and other workers (30). Having well-defined roles can help foster a more personal connection with the work and pa-

tients. The correlation between depersonalization and role conflict for both groups is that role conflict may create emotional strain, leading to a more impersonal and detached approach to work and patient interactions. On the other hand, a positive correlation with workload in the case of non-medical personnel suggests that workload can be emotionally overloading and lead to a lack of emotional investment in interactions, which might contribute to depersonalization. Findings are supported by previous research where we can see strong correlations between psychosocial risk factors and burnout (31).

Previous results indicated that healthcare professionals with higher levels of emotional intelligence were less prone to experiencing emotional exhaustion and depersonalization. Additionally, they were more likely to experience a sense of personal accomplishment in their roles. This suggests that emotional intelligence plays a significant role in influencing the experience of burnout among health care professionals, positively impacting their well-being and job satisfaction (32).

Personal accomplishment correlates with the three dimensions of emotional intelligence. Healthcare professionals who possess higher levels of emotional intelligence are more likely to experience a sense of personal accomplishment in their roles. There are several reasons why emotional intelligence contributes to this feeling of accomplishment: improved patient relationships by establishing better connections with their patients. They can understand and empathize with patients' emotions, concerns, and needs, leading to more effective communication and a higher level of patient satisfaction. When healthcare professionals see the positive impact of their care on patients' lives, their sense of accomplishment is enhanced. A person with higher level of emotional intelligence could develop effective conflict resolution, so they can resolve disagreements with patients, colleagues, or supervisors in a respectful and empathetic manner. Successfully resolving conflicts augments their sense of competence and accomplishment in handling difficult interactions.

Another positive aspect of emotional intelligence is personal growth and development. Emotional intelligence involves continuous self-improvement and learning. Healthcare professionals who enthusiastically work on developing their emotional intelligence are more open to feedback, receptive to learning opportunities, and eager to adapt and grow in their roles. This dedication to personal development contributes to a greater sense of accomplishment in their professional journey.

Regarding emotional exhaustion and emotional intelligence, significant and negative correlations are observed only among medical staff with emotional clarity and emotional repair. In contrast, there are no significant statistical correlations among non-medical staff. Similarly, depersonalization shows significant statistical correlations only among medical staff, with all relationships being negative. However, a health care professional who possesses the ability to understand and regulate their emotions during these service operations is more likely to reduce their experiences of emotional exhaustion and depersonalization. Moreover, they are more likely to enhance their sense of personal accomplishment. This indicates that emotional intelligence and the capacity to effectively handle emotions in the context of their work can play a crucial role in minimizing

burnout and enhancing job satisfaction among health care professionals (32). This finding is in line with Salovey *et al.*'s (33) assertion that individuals who possess the ability to regulate their emotional states tend to be healthier. They achieve this by accurately perceiving and evaluating their emotional states, knowing how and when to express their feelings, and effectively managing their mood states. This suggests that health care professionals with higher emotional intelligence are better equipped to handle the challenges and stressors of their profession, leading to lower emotional exhaustion levels and potentially better overall well-being (32).

In our study, significant negative correlations were found between emotional intelligence and the two negative dimensions of burnout, namely, emotional exhaustion and depersonalization, only in the case of medical personnel. These results are confirmed by previous literature, which revealed significant correlations between emotional intelligence and the dimensions of burnout among nurses. Specifically, there was a significant inverse relationship between emotional intelligence and emotional exhaustion, indicating that higher levels of emotional intelligence were associated with lower levels of emotional exhaustion among nurses. Similarly, there was a significant inverse relationship between emotional intelligence and depersonalization, suggesting that higher emotional intelligence was linked to lower levels of depersonalization. Personal accomplishment significantly correlates with emotional intelligence. Results are in line with other studies that revealed a significant direct correlation between emotional intelligence and personal accomplishment among nurses (34). This means that higher emotional intelligence scores were associated with a greater sense of personal accomplishment among healthcare personnel. In a study investigating the connection between Emotional Intelligence (EI) and burnout among healthcare professionals with a focus on demonstrating how EI serves as a protective factor against the risk of burnout, a significant relationship between EI and burnout was highlighted, emphasizing the potential role of emotional intelligence in mitigating burnout among healthcare professionals. The sample for this survey consisted of health professionals, including doctors, nurses, and other caregivers, totaling 148 employees (35).

Strengths and limitations of the study

This is one of the few studies conducting a comparative analysis of medical and non-medical staff in Romania. However, there are certain limitations that need to be acknowledged. Firstly, the use of the snowball sampling method to select participants could introduce bias into the results. Additionally, some variables were measured with only a few items, and only specific dimensions of the scales were considered, which may have restricted the scope of the research. Another limitation is the reliance on self-reporting, which could lead to overestimated correlations and misinterpretations of the data. To obtain a more comprehensive understanding of healthcare institutions, future studies should also include auxiliary staff from both public and private medical units in Romania, as this group was not examined in the current research. It would be valuable to investigate whether the proposed intervention model yields different results for these employees. To accurately reflect reality, longitudinal research is necessary to ex-

plore how various factors impact the perception of burnout and psychosocial risks among healthcare employees at different points in time.

CONCLUSIONS

Based on the findings of this study and consistent with previous scientific literature (36-39), it can be concluded that psychosocial risks and emotional intelligence play a significant role in predicting burnout. It is important to note that emotional intelligence is not limited to specific job roles or professions; both medical and administrative personnel can benefit from evolving their emotional intelligence to enhance their interactions with patients, colleagues, and themselves. Moreover, these distinctions might not apply generally to all individuals within these roles, as emotional intelligence can vary greatly from person to person, regardless of their job title. The medical staff experiences a higher sense of organizational justice and personal accomplishment compared to the non-medical staff. Regarding the negative dimensions of burnout, higher levels of emotional exhaustion and depersonalization have been recorded among non-medical personnel. Additionally, higher scores have been observed among administrative staff for the dimension of emotional attention or emotional intelligence. As for the other psychosocial risks, role conflict has been reported to have higher values among administrative personnel, as has workload. In both groups, when there is a high level of emotional exhaustion or depersonalization and an increased sense of role conflict or workload, perceived organizational justice and role clarity are lower. On the other hand, when personal accomplishment is high, there is also a higher level of role clarity (for both groups) and a greater sense of organizational justice (for medical personnel).

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

PHYSICAL VIOLENCE IN THE HEALTHCARE SYSTEM - AN EPIDEMIC WITH DIRE CONSEQUENCES ON NURSES (Abstract): Workplace violence against nurses is a serious problem, affecting healthcare systems worldwide. Physical violence is a visible form of abuse, although little is known about its prevalence and consequences. Nurses, acting as intermediaries between doctors and patients, are particularly vulnerable due to their frontline roles, engaging with diverse individuals in emotionally charged environments. The aim of this study was to analyze the incidents of physical violence against nurses in Romania, assessing their frequency, characteristics and consequences and the victims' sociodemographic and occupational profiles. **Materials and methods:** We conducted a quantitative, prospective study, using the Romanian version of the questionnaire developed by International Labor Organization, International Council of Nurses, World Health Organization, and Public Services International regarding workplace violence in healthcare. The survey, distributed online to Romanian nurses and doctors, collected data on the workplace violence incidents, the victims and aggressors, and the consequences of these occurrences. **Results:** 2.4% of the 7,203 nurses who participated in our study declared that they experienced physical abuse in the previous year. Most incidents were committed by patients and their relatives, inside medical facilities. Both physical and psychological consequences of the violence incidents were mentioned in varying degrees and significant correlations were found between the assaulted nurses and their gender, professional experience, work sector, and working shifts or nights. **Conclusions:** This research reveals the reality of the physical violence against nurses in Romania and emphasizes the importance of addressing this phenomenon by the healthcare system. Furthermore, our findings indicate the need for preventative initiatives and measures towards workplace violence in healthcare. **Keywords:** WORKPLACE, HEALTHCARE SYSTEM, PHYSICAL VIOLENCE, NURSES, CONSEQUENCES.

The World Health Organization defines workplace violence as "incidents in which staff are abused, threatened, or attacked in circumstances related to their work, including during travel to or from home, and which involve a threat to their safety, well-being, or health" (1).

Even though workplace violence in the medical field is common, it is often underreported, and its consequences are difficult

to estimate. Physical violence is one of the many forms of workplace violence and it is the most noticeable because of its consequences, which can range from minor injuries to serious ones. Moreover, in addition to physical injuries victims of physical abuse may suffer from psychological consequences, including anxiety, depression and burnout, and may be unable to perform their duties or they may need time off work (2). The threat of workplace violence against any member of the medical personnel can be translated to the inability of the healthcare system to protect its employees and endangers the quality of the medical care (3).

Nurses are particularly vulnerable to workplace violence, ranging from verbal abuse to physical assaults, due to the fact that they act as a vital intermediary between the doctors and the patients and their families. Moreover, nurses have to provide care in an emotionally dominated environment and to constantly engage with different types of people. Therefore, physical violence against nurses is a serious and widespread concern for healthcare systems around the globe (4, 5).

One study conducted in Germany reported that 70.7% of the medical staff had been the victim of physical violence and 89.4% of verbal abuse (2). Similar results were observed in a study conducted in the emergency room of a Turkish hospital, where 91.4% of the nurses reported verbal abuse and 74.9% reported physical abuse during the previous 12 months (6).

A Chinese study that documented the violent episodes against medical personnel during a time span of 10 years reported 29 murders and 52 serious injuries(5), while 70% of the Singaporean medical personnel experienced physical abuse, even though these actions were under-reported (7).

Workplace violence in healthcare has been under-investigated in Romania. According to data provided by a 2015 study conducted by the College of Physicians from Bucharest, 10.2% of physicians reported experiencing physical aggression(8). Furthermore, a study involving resident physicians from the “Carol Davila” University of Medicine and Pharmacy, Bucharest, revealed that 8.4% of the participants experienced physical aggression from a patient during their residency (9). The scarcity of the studies that explore workplace violence in the Romanian healthcare system, particularly that of physical violence against nurses, emphasizes the need for further research.

The aim of this study was to analyze the incidents of physical violence against nurses in Romania, assessing their frequency, features and consequences (both physical and psychological) and also the victims’ sociodemographic and professional characteristics.

This study is part of the doctoral research entitled "Research on violence against medical personnel in Romania". The doctoral research has been carried out at the Doctoral School of “Grigore T. Popa” University of Medicine and Pharmacy from Iasi and aims to investigate violence against medical personnel (doctors and nurses) in Romania.

MATERIALS AND METHODS

Study design

We carried out a quantitative, retrospective study in which data was collected with a questionnaire that was distributed to all nurses and doctors in Romania.

Data Collection

The survey instrument used is the

Workplace Violence in the Health Sector Country Case Studies Research Instruments - Survey Questionnaire (10). The questionnaire was developed by International Labor Organization, International Council of Nurses, World Health Organization, and Public Services International in 2003 and it was translated by the authors of this study to Romanian with the approval of the World Health Organization. The complete questionnaire includes 130 questions, divided into 7 sections: the first one regarding the sociodemographic and professional characteristics of the participants, the next 5 sections exploring different types of physical and psychological violence (i.e., verbal abuse, intimidation, racial harassment, and sexual harassment) experienced by the participants at the workplace in the previous year, with a focus on prevalence, perpetrators' characteristics, effects, consequences and actions that were taken by the participants and by the institutions; the last part of the questionnaire investigates workplace policies and working conditions, and it also contains questions about the participants' opinions about the factors contributing to violent incidents. Each section starts with the definitions of the investigated notions, in order to limit the personal interpretations of the participants.

The questionnaire was distributed through Google Forms (access link: https://forms.gle/JtzMi3sfa2Yd6a6k9) to all doctors and nurses in Romania, who were affiliated with the national professional associations, regardless of the medical institution where they worked. In the nurses' case, invitations to participate to this study were sent via e-mail to all members of the Romanian Order of General Nurses, Midwives and Medical Assistants, that included the link to our questionnaire. Afterwards, the access link was distributed online in the main Facebook group of Romanian nurses with approximately 40,000 members. The access link was valid for 2 months, between 10.02.2022-10.04.2022.

Data Analysis

Data was analyzed with the IBM *SPSS Statistics 20* software, using descriptive statistics to calculate the prevalence rates, frequencies and percentages and also univariate analyses. The threshold for statistical significance was set at a p-value below 0.05.

Ethical Considerations

The doctoral research was approved by the Research Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy from Iași, as indicated by the Approval No. 52/21.02.2021. Prior to accessing the questionnaire, each participant was asked to read the information about the study mentioned on the first page of the questionnaire and to consent to participation. The responses provided by the participants were anonymous.

RESULTS

In this article the authors present the results concerning the incidents of physical violence against nurses and their consequences, as well as the aspects related to the organizational dynamics of their work environments.

Participants

The study group consisted of 7,203 nurses, 6,675 (92.7%) of them being women. The majority of the participants worked in public healthcare facilities (75.2%), in shifts (66.1%) and had direct interactions with patients during their work (81.7%). Their workplace is usually the hospital (59%), 31.8% of the participants having

had over 20 years of experience in the healthcare system. The socio-demographic and professional characteristics of the participants are further detailed in first table.

TABLE I.
Socio-demographic and professional characteristics of the study population

Characteristics		N =7203	%
Sex	Male	528	7.3
	Female	6675	92.7
Professional experience	Less than 5 years	1844	25.6
	Between 6 and 10 years	1113	15.5
	Between 11 and 15 years	941	13.1
	Between 16 and 20 years	1016	14.1
	More than 20 years	2289	31.8
Work sector	Private institutions	1782	24.7
	Public institutions	5415	75.2
	Not disclosed	6	0.1
Work in shift	No	2439	33.9
	Yes	4764	66.1
Night shift (between 18:00 and 7:00)	No	3258	45.2
	Yes	3945	54.8
Direct interactions with patients	No	1319	18.3
	Yes	5884	81.7

	Volunteer	185	2.6
	Nurse privately employed	46	0.6
	Senior Manager	33	0.5
	Not disclosed	6	0.1

Prevalence and characteristics of the violent incidents

According to the definition provided in the questionnaire, physical violence is "the use of physical force against another person or group, that results in physical harm, sexual or psychological harm. It can include beating, kicking, slapping, stabbing, shooting, pushing, biting, and/or pinching, among others".

Among the nurses participating in this study, 172 were victims of a physically violent incident at the workplace, which amounts to 2.4% of the total number of participants. However, 335 (4.7%) of the nurses participating in our study witnessed physical violence at work (tab. II). Moreover, the prevalence of incidents differs between males and females, with a higher prevalence observed among males (4.4%)

compared to females (2.2%).

Most of the physical violence events occurred within the medical institutions (79.7%) and the aggressors were either the patients (66.3%) or their relatives (11%).

Half of the violent incidents could have been avoided according to the nurses involved. The main characteristics of the physical violence events mentioned are summarized in table III.

TABLE II.

Frequency and percentage of physical violence in the study group

Physical violence at the workplace		N (7203)	%
Experienced at least a physical violent incident at work in the last year	No	7031	97.6
	Yes	172	2.4
Witnessed at least one physically violent incident in the last year	No	6868	95.3
	Yes	335	4.7

TABLE III.

Characteristics of the reported physical violence incidents

Characteristics		n (172)	%
Location	Within the medical institution	137	79.7
	At the patient's home	15	8.7
	Outside the medical institution - on the way to work	7	4.1
	Outside the medical institution - at your home	6	3.5
	Unspecified location	7	4.1
Perpetrator	Patient	114	66.3
	Patient's relatives	19	11
	Staff member, superior or colleague	23	13.4
	Member of the general public	11	6.4
	Not disclosed	5	2.9
Opinion on whether the event could have been prevented	No	86	50
	Yes	86	50
Presence of Physical Injuries	No	126	73.3
	Yes	46	26.7
Time off work needed	No	141	81
	Yes	31	18

Significant results from the Chi-Square statistical analysis revealed associations between the physical violence and some of the characteristics of the study population. Thus, significant correlations were observed for gender ($p = .002$), professional experience ($p = .028$), work sector ($p = .014$), working in shifts ($p = .000$), night shifts ($p = .000$), and working in hospitals ($p = .000$) (tab. IV). In our study female nurses, with little work experience, that worked in public institutions, in shifts and at night and that interacted directly, constantly with patients have experienced physical violence at their workplace.

TABLE IV.
Socio-demographic, professional characteristics of the victims of physical violence - results of the chi-square statistical test

Characteristics		n=172	%	p-value
Gender	Male	23	13.4	.002

Consequences of the violent incidents on victims

Among the nurses who sustained a physically violent incident, 46 nurses (26.7%) suffered from physical injuries after the violence, and 31 (18%) needed days off work because of them (tab. 3).

In fifth table, we present the psychological effects of physical violence events reported by the participants. The table displays the frequencies and percentages of responses to questions assessing the extent of psychological impact, categorized into “Not at all”, “Slightly”, “Moderately”, “Quite a lot”, and “Very much”. Our results show that 8,7% of the victims experienced very often distressing thoughts or memories. Nurses reported feeling very much “on guard” (11.6%) or being very much affected by the feeling that their activities require additional effort (7.6%). Overall, responses indicate varying levels of psychological distress, with most participants reporting some degree of psychological impact of the violent incident.

TABLE V.
Psychological consequences of physical violence

Psychological Consequences	Not at all (N, %)	Slightly (N, %)	Moderately (N, %)	Quite a lot (N, %)	Very much (N, %)
(a) Repeated memories, thoughts, or images	57 (33.1%)	37 (21.5%)	41 (23.8%)	22 (12.8%)	15 (8.7%)
(b) Avoidance of thoughts or discussions	58 (33.7%)	40 (23.3%)	45 (26.2%)	19 (11.0%)	10 (5.8%)
(c) Feeling "super-alert" or "on guard"	51 (29.7%)	30 (17.4%)	47 (27.3%)	24 (14.0%)	20 (11.6%)
(d) Feeling that activities require extra effort	56 (32.6%)	32 (18.6%)	51 (29.7%)	20 (11.6%)	13 (7.6%)

DISCUSSION

Workplace violence in healthcare affects all categories of staff, with nurses being at the forefront. The aim of this study was to evaluate the prevalence, characteristics and consequences of the physical violence incidents the nurses in the Romanian healthcare system, and also the socio-demographic and professional characteristics of the victims.

Our study included a diverse group of nurses working in various environments, with different professional experiences, in order to provide a global perspective of the workplace violence phenomenon in the Romanian healthcare system. The results showed that 2.4% of participants claimed they had been a victim of physical violence at work in the previous year, with 4.7% of them witnessing it. The difference in the percentages highlights the fact that incidents of physical violence happen even when coworkers are around.

According to a study conducted in the USA, 25% of the participating nurses reported having had experienced physical violence (11). A single-hospital study conducted in Great Britain showed that 63% of the medical staff had missed work due to physical abuse in the last month (12). Studies pinpointed hospitals as environments associated with higher prevalence of physical violence against medical staff (6, 13).

The majority of the physical violence incidents reported by nurses in our study occurred in public medical institutions, with a significant statistic correlation between being employed in hospitals and the risk of being a victim of physical workplace violence. This is consistent with findings of other studies, which emphasize the role of the organizational deficiencies - such as the lack of security personnel, stressful work environment, insufficient staffing and prevention policies, that contribute to the occurrence of violent incidents against medical staff (12, 14).

Our study revealed that most of the physical violence incidents were initiated by patients (66.3%) and their relatives (11%). This finding is mentioned also in studies conducted in other countries, with patients and their relatives being the primary source of workplace violence against medical personnel, especially physical violence (6, 14).

The nurse - patient relationship is influenced by the emotional vulnerabilities of the patients and their families, but also by the social constructs regarding the position of nurses. Most nurses interact directly with patients, as demonstrated by our

study, and this dynamic may result in a mutually frustrating relationship between them and patients and their relatives (14). The perceived role of the nurse is that of an employee meant to satisfy both the doctor's and the patient's requirements; therefor the patients and their families often consider the healthcare staff, and nurses in particular, as nothing more than service providers that must be responsive to their needs (15). This view overlooks and ignores the importance of internal policies, organizational procedures, and medical judgments that are involved in the patient-medical personnel relationship.

Another important factor that influences the nurse - patient relationship is the different perspectives regarding the medical situation. While nurses may view the medical process as a routine, patients and their families perceive it as extremely stressful and even life-threatening. This difference can be interpreted by the patients as a proof of nurses' lack of compassion, empathy and engagement (16).

According to our results, half of the violent incidents could have been avoided. This proves that nurses can identify viable solutions that could decrease the risk of physical violence at their workplace. However, this aspect requires further research in order to implement efficient policies and initiatives to prevent and address instances of physical violence in healthcare institutions.

In terms of socio-demographic characteristics of the victims, significant correlations were found between the occurrence of the physical violence and the victims' gender, professional experience, and work sector. Thus, our study showed that the newly hired employees (28.8%) are the most commonly involved in violent incidents. This happens because nurses with little experience in the field might find it more difficult to communicate with patients and their families, which could be perceived as insecurity and a lack of good patient care (15).

Our study shows that both female and male nurses can experience physical workplace violence; almost 90% of the victims were female, yet the male nurses that participated in our study reported physical violence more often (4.4% of men compared with 2.2% of women). On the one side, female nurses might be subjected to stereotypes about their role; in our society, this translated also to the way the victims think about the incident: female victims often state the unpredictable nature of the assaults and think of them as aspects of their professional role, while male nurses describe them factual, including data about the witnesses and the consequences (17). This result must be interpreted cautiously due to the difference in sample size, i.e., there are fewer men involved in our study than women.

A particularity of working in the medical field is the work in shifts and at night. These two parameters were found in our study to be significantly correlated with the risk of nurses to be assaulted at work. This finding is supported by other studies that also correlate them with longer waiting times and lower tolerance levels of patients and their relatives (18, 19). Moreover, the night shifts are frequently understaffed and this aspect adds to the unique characteristics of the patients examined at night, i.e., alcohol consumption, altered general status, and agitation (18). This finding of our study suggests the need of preventive actions and special training actions, emphasizing the role of the institutional policies (18).

There are many different types of consequences that can arise from physical violence. First, there are the immediate physical consequences. In our study, about one-third of the attacked victims suffered physical injuries, and 18% of them even needed time off. This finding is in line with the results of other studies that mention that these traumatic events are more often associated with work interruption (6,20). The physical consequences are the most commonly mentioned in the literature, and they have an impact not only on victims, but also on the relationship between coworkers, patients, and their families as well as the work environment (2, 14). These effects are also linked to increased levels of stress and insecurity in the workplace (7, 21).

In terms of psychological consequences experienced by nurses who have been physically harmed, our study showed that constant memories and uncomfortable thoughts, along with the avoidance of conversations about the incident appear as a result of the violence incidents. This type of consequences is also revealed by the literature, especially in situations involving physical violence. Nurses frequently express feelings of frustration, rage, and anxiety (2). Other studies showed that these feelings regarding the violent incidents can be viewed as post-traumatic stress symptoms (22, 23), reaffirming the need for further change.

The constant feeling of being "on guard" that some nurses stated they felt after the physical incident further supports the idea that they perceive their workplace as unsafe, and any interaction as a possible source of violence (22). This increased alertness can have a negative effect on the nurses' relationships with patients, family members, and coworkers, adding to stress and burnout (2, 3). Physical violence in the workplace can also lead to a decrease in motivation, engagement, and overall job satisfaction of nurses, which can impact the quality of life as well as the quality of the medical care as a whole (20,21). Burnout syndrome and the desire to quit the workplace are also linked with physical violence sustained at work (24).

Strengths and limitations

One strength of our study is the large number of participants and the national coverage of the study. The large number of information collected on the violent incidents at the workplace and their consequences, coupled with the large number of participants may provide a quite accurate picture of the current situation in our country.

We attempted to reduce the memory-related bias by restricting our analysis to events that occurred in the last year and gathering detailed information. We encouraged participants to be more open about their experiences with workplace violence by choosing an anonymous survey. One limitation of our study is that we did not select representative samples of nurses from various medical specialty, as the questionnaire was distributed online by the professional association to all nurse in Romania. As a result, the study might not capture the nuanced variations that could exist among different medical specialties, since the experiences, perspectives and practices of nurses may vary across different branches in healthcare.

CONCLUSIONS

The findings of this study show that workplace violence against nurses, and in particular physical violence, is a serious problem of the Romanian healthcare sys-

tem, providing an analysis of its prevalence, features and consequences.

In our study, nurses who work at night, in shifts, or in a hospital, with limited work experience were more prone to physical workplace violence; the perpetrators were usually the patient and their relatives, contributing to the nuances of this problem. The consequences of the violent events span from physical ones, that might even need time off work, to psychological ones (distressing thoughts and memories, increased alertness), which are often difficult to measure, but all with a definite impact on the quality of life of nurses and the quality of care provided to patients.

To address this issue effectively, the results of our study can be further expanded and serve as the starting point for discussions regarding initiatives, policies and programs targeted at preventing and solving workplace violence against healthcare personnel. On the one side, it becomes essential to promote a culture where workplace violence is not tolerated, starting with organizational change, in terms of security levels, facilities improvement, and policies dedicated to reporting workplace violence. In addition, the wide range of consequences mentioned in our study emphasizes the urgency of providing support to victim; offering professional care becomes crucial in order to minimize the impact of workplace violence on their work and overall well-being.

In conclusion, tackling workplace violence calls for actions initiated from the medical institutions and expanded in order to encompass the whole healthcare system. To build work environments where the safety and wellbeing of healthcare professionals are promoted, society as a whole must also be involved.

CONFLICT OF INTEREST AND FUNDING

The authors declare no conflict of interest regarding this article. The authors declare that all the procedures and experiments of this study respect the ethical standards in the *Helsinki Declaration* of 1975, as revised in 2008(5), as well as the national law. Informed consent was obtained from all the participants included in the study. No funding was received for this study.

THE INFLUENCE OF SYNTHESIS TEMPERATURE ON A POLYURETHANE CARRIER USED FOR THE TRANSFER OF 2'-DEOXYCYTIDYLIC ACID (Abstract): 2'-Deoxycytidylic acid, a nucleotide based on cytosine, deoxyribose and phosphate group, is a fundamental unit of nucleic acids. Various supplements containing nucleosides or nucleotides have been formulated for patients with genetic defects resulting in the presence of incorrect nucleotides. The **aims** of the current research were to obtain and to characterize polyurethane transporters that can be used for the transfer of nucleotides through body membranes. **Materials and methods:** Three samples have been developed based on different synthesis temperatures and the effects of this parameters on the properties of the final products were assessed; there were measured the solubility, pH, refractivity index, the encapsulation efficacy and release profile, size distribution and surface charge, cells proliferation and irritation tests on mice skin. **Results:** The obtained mean values show that were obtained almost neutral acido-basic particles with sizes range from 126 to 814 nm; Zeta potential values indicate the tendency to form clusters in samples with synthesis temperatures above 40°C, while UV-Vis evaluations show an approx. 60% encapsulation efficacy. Regarding the biosafety profile of the samples, the assays on cells culture and mice skin did not elicit important side effects at tested concentration. **Conclusions:** The findings of this preclinical study suggest that polyurethane carriers exhibit promise as a therapeutic or preventative measure for a range of diseases by addressing genetic irregularities, demonstrating their safety for such applications. **Keywords:** CELLS CULTURE; DRUG DELIVERY; MICE SKIN; UV-VIS; ZETASIZER.

The monomers of DNA, that contain a base (adenine, cytosine, guanine, thymine), a sugar (deoxyribose) and phosphate residues, are called nucleotides. They present similar structures with nucleosides, biological molecules known as glycosylamines,

but lacking phosphate functional groups (1). These compounds serve as units in the macromolecular chains of the nucleic acids, the most important molecules for the continuity of life. 2'-Deoxycytidylic acid, also known as 2'-Deoxycytidine-5'-monophosphate (fig. 1), is formed by the reduction of cytidine-monophosphate, the product of hydrolysis of cytidine triphosphate and cytidine diphosphate; it may be *de novo* synthesized in a series of steps via aspartate transcarbamylase and dihydroorotate as other pyrimidines, but it also be derived from RNA-rich dietary sources (2).

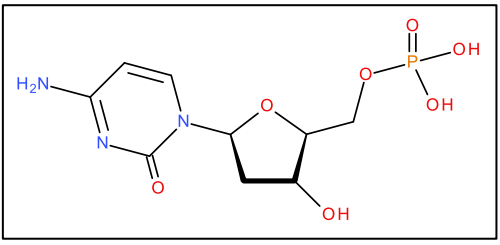

Fig. 1. The chemical structure of 2'-Deoxycytidylic acid

Recent studies present a correlation between nucleosides and brain diseases: modified adenosine levels can cause seizures, while changes of the astrocyte-based adenosine cycle were found in epileptic brain (3), guanosine decrease the number of seizures determined by glutamatergic agents and it is neuroprotective in brain hypoxia and ischemia (4). Inosine is discharged from neurons in the presence of extracellular calcium depending on the N-methyl-d-aspartate receptor (5), while cytidine and uridine have an impact in neurodegenerative conditions due to their contribution to brain phosphatidylethanolamine and phosphatidylcholine levels via the Kennedy pathway (6). D. Boison has described the nucleoside metabolism and several nucleoside-based therapies to treat brain diseases (7), but he also mentioned that nucleoside transporters represent a very interesting research theme.

The majority of naturally occurring nucleotides, as well as many nucleotide medications, possess a strong affinity for water and do not spontaneously cross lipid bilayers. Such transportation, if it occurs at all, typically requires mediation or active transport mechanisms (8). The carriers used for the transport of various biologically active substances are the results of the connection between nanotechnology, medicine and pharmacy; organic and inorganic delivery systems, based on nanocapsules, nanodots, nanofibers, dendrimers and matrices, were developed and characterized in the last decades (9). Polyurethane (PU) drug delivery systems were developed starting with the end of the last century; their first syntheses were based on raw materials with aromatic character such as methylene-diphenyl diisocyanate and toluene diisocyanate and the obtained structures were large and presented low penetration rates. At the beginning of this century, K. Bouchemal and her team (10-12) described the synthesis of PU capsules with much smaller sizes based on an interfacial polyaddition process combined with a spontaneous emulsification.

Our research team has modified the previous recipes in order to avoid the use

of raw materials with carcinogenic potential, to decrease the number of the chemical compounds, to enhance the encapsulation efficacy and the release profile; thus, we have synthesized and characterized PU carriers applicable for various extracts and drugs (13-15). The synthesis temperature represents a very important parameter that can have a huge impact on the properties of the final products; R. Fiorio *et al.* (16) showed in a study on the impact of synthesis temperature on PU samples that the glass transition was not modified, but activation energy (E_a) has changed and many side reactions (other than formation of urethane groups) have appeared. The objectives of the current research were to synthesize and to characterize PU structures obtained at different temperatures and to evaluate the impact of the temperature on the transport potential of nucleosides.

MATERIALS AND METHODS

Chemicals, cells culture, and mice

Sorbitane trioleate or Span® 85 was purchased from Sigma (Taufkirchen, Germany), while isophorone diisocyanate (IPDI), polyethylene glycol (PEG 400), polycaprolactone diol (PCL Mn~530), 1,6-hexanediol (HD), tris(hydroxymethyl)aminomethane (THAM), inorganic salts (NaCl, KCl and $MgCl_2$, Na_2HPO_4, K_2HPO_4, KH_2PO_4 and $NaHCO_3$) and 2'-Deoxycytidylic acid as sodium salt were acquired from Sigma Aldrich (St Louis, USA) and acetone from Honeywell Riedel-de Haen (Seelze, Germany). All the reagents were analytical grade purity and they were used without any previous purification; a JP Selecta Dest-4 distiller was involved to obtain double distilled water.

For the cytotoxicity evaluation, HDFa (Human Dermal Fibroblast) cell line was purchased from Invitrogen (Waltham, USA), while all the reagents (culture media, antibiotics, FBS, PBS, trypsin-EDTA and MTT solution, DMSO) and culture supplies (culture flasks, Pasteur pipettes, pipette tips, microplates) were achieved from Thermo Fischer Scientific (Waltham, USA).

Female, 6-8-week-old CB17SCID mice were purchased from Charles River (Sulzfeld, Germany). They were kept under standard conditions - temperature (24± 2°C), humidity (55±5%), 12h light/dark cycle.

Synthesis of the transporter

The PU synthesis is based on a polyaddition reaction between an active hydrogen-containing phase (ether- and/or ester-polyols) and a di- or tri-isocyanate. In the current research, an aliphatic isocyanate (IPDI) was used as the organic phase. In the aqueous phase, the ratio between PEG 400 and PCL was established according to our previous results (17,18) and taking into consideration that this balance has a huge impact on the drug release kinetics.

The inorganic phase (1.8 mL HD, 3.5 g PEG 400, 3.0 g PCL, 1.2 g THAM, 1.5 mL Span® 85 and 0.5 g 2'-Deoxycytidylic acid sodium salt) was dissolved in 35.0 mL double distilled water and stirred at 375 rpm and 35±0.2°C overnight. In parallel, three isocyanate solutions obtained from 6.0 mL IPDI in 25.0 mL acetone were homogenized in different flasks at 345 rpm and 40±0.2°C for 30 minutes. Then, the aqueous phase was divided equally among the three flasks and their contents continued to be stirred at 350 rpm using different temperatures (**Tab. I**) for 3 hours to complete the synthesis of the macromolecular chains; the temperatures were precisely monitored using a P700 Universal thermometer from Dostmann electronic GmbH

(Wertheim, Germany). In the end, the content of the three flasks was sonicated for 5 min using a Bandelin Sonorex Digitec bath sonicator (Berlin, Germany).

TABLE I.
The synthesis temperature used for every sample

Samples code	Synthesis temperature °C
PU_T1	25
PU_T2	40
PU_T3	55

There were obtained white suspensions that were passed through 0.22 μm PVDF sterile syringe filters from Merck Millipore (Darmstadt, Germany) during a washing process with a mixture of water-acetone (1: 1.3, v/v) and finally they were centrifuged at 2,200 G using an Ika Mini G microcentrifuge (Staufen, Germany) in order to concentrate the samples; the water-acetone mixture used during the washing process was later analyzed in order to established the free drug content. In the end, the samples were dried in borosilicate glass Petri dishes at room temperature to constant mass (approx. 120 hrs.).

Samples Stability

The samples stability was assessed by using an aliquot of every sample that was stored at different temperatures: 8±0.5°C, 25±0.5°C and 40±0.5°C with 65±3% relative humidity for one month; color as maximum absorbance and electrical conductivity of samples were recorded every third day using a SI Analytics UVi Line 9400 spectrophotometer (Mainz, Germany), respectively a Jenway Bench 4010 Conductivity meter (Staffordshire, UK) at 25°C in aqueous solutions (0.8 mg mL^{-1}).

pH, Refractive index
and Solubility Measurements

pH of every sample was measured using a Mettler Toledo FiveGo F2 portable pH meter (Schwerzenbach, Switzerland), In-Lab® Expert Go Sensor and aqueous solutions with the same concentration (0.8 mg mL^{-1}) at 25°C.

2-3 drops of every aqueous solutions and a Kern digital refractometer (Balingen, Germany) were used to assess the refractive index of the synthesized samples at room temperature.

For the solubility in distilled water, acetone, and DMSO, based on a procedure already described by our team (13), 5.0 mg dried product were dissolved in the respective solvent in 20 mL glass vials with screw caps at room temperature; the volume of every solvent was registered when a single, clear liquid phase with no distinct solid or gel particles was recorded.

Drug Loading

The successfully entrapped amount was found by reporting the quantity of the free drug to the total added amount, Equation 1:

$$DL\% = \frac{TA - FD}{TA} \cdot 100$$

where DL% is the drug loading percentage, TA and FD are the total amount and the amount of free drug (mg).

These amounts were calculated using the Beer-Lambert law: a calibration curve (the absorption values *vs*. drug concentration) was initially drawn.

Drug Release Profile

The cumulative drug release (CDR) was obtained by monitoring the amount of 2'-Deoxycytidylic acid sodium salt that was released during the PU transporter exposure to a simulated body fluid (SBF) prepared according to F. Baino and S. Yamaguchi (19): 6.6 g NaCl, 2.3 g $NaHCO_3$, 0.4 g KCl, 0.1 g Na_2HPO_4 were mixed with 960 mL double distilled water in a 1000 mL-capacity flat bottom flask and heated at

37°C; then 0.3 g $MgCl_2$ hexahydrate, 0.4 g $CaCl_2$ dihydrate, 0.1 g Na_2SO4, 6.1 g Tris were added and the pH was adjusted to 7.4 with HCl 1M. The samples were maintained inside SBF for 5 days at 37.0±0.5°C and 150 rpm; 1.0 mL SBF was replaced daily with fresh degrading environment and UV-Vis spectroscopy was employed to quantify the released drug.

The Penetrability Rate

A Franz-cell system (Φ 15 mm, diffusion area of 1.77 cm^2 and the receptor volume of 12.0 mL) and a PVDF artificial membrane Spectra/Por® were used to test the transporter permeation. The receptor chamber was filled with PBS and the experiment was done at 25±1°C; at every 10 hours, 1.0 mL liquid from the receptor chamber was replaced with fresh buffer and spectral analyzed.

Zetasizer Tests

The size and surface charge of PU transporter were assessed through dynamic light scattering technique on a Cordouan Technol. system (Pessac, France); the main input parameters that were set for the determination of particles size and its distribution were the temperature (25°C), time interval (18 μs), channels number (460), laser power (80%), acquisition mode (continuous) and analysis mode (Pade-Laplace). The following parameters were set to detect the surface charge: temperature (25°C), applied field (automatic), medium resolution (0.8 Hz), measures number/sequence (3), laser power (80%), Henry function (Smoluchowski), cuvettes (quartz).

Cells Viability

HDFa cells (passage 3) were used as follows: the cells were seeded in a culture medium supplemented with 10% FBS and 1% penicillin-streptomycin; the medium was changed at 2-3 days and the proliferation was determined by the MTT technique. Cells from the HDFa line (1x10^5 cells/mL) were seeded in 100 μL medium in 96-well plates. Cells were allowed to adhere for 24 hrs. in the incubator. After 24 hrs., the growth medium was changed with the test compounds (90 μL medium+10 μL sample); the tests were performed in triplicate at 24 and 72 hrs. after the treatment.

Skin Irritation Evaluations

The irritation potential on sensitive mice with and without hair is often used as a parameter that describes new synthesized chemical compounds. In the current study, 20 mice were divided into five groups, labeled as the samples code (tab. I) and two special groups (control group – mice treated only with the solvent, and SLS group – mice treated with a 2.0% sodium lauryl sulfate solution, a recognized skin irritant). The hair from the back of CB17SCID mice (approx. 3 cm^2) was shaved at the beginning of experiment and then every 5 days. The application of the studied samples (40±5 μL once) was done on the back skin every third day for 15 days and the measurements of parameters were performed 30 minutes later. The changes of skin erythema and hydration were monitored using a Multiprobe Adapter System (MPA5) from Courage-Khazaka (Koln, Germany) equipped with a Mexameter® MX 18 and a Corneometer® CM 825 probes.

Statistics

Data analyses were performed using IBM *SPSS Software version 27.0.0.0* (Armonk, NY, USA). The continuous variables are presented as mean and standard error (SE). Non-parametric tests were used to evaluate the significance due to the small datasets. $p< 0.05$ was considered statistically significant. The charts were modeled in Excel - Microsoft® Office Professional Plus

2019 from Microsoft Corp. (Washington, USA).

Ethics approval

The proposal of this research was checked and approved by the Ethics Committee of "Victor Babes" University of Medicine and Pharmacy Timisoara (Approval No. 42, 29th of October, 2021).

RESULTS

Stability of PU transporter

It is well known that polymeric materials present a huge stability in time; however, a few degradative processes based on the thermal and/or UV radiation, the microorganisms attack and hydrolytic conditions can alter the properties of macromolecule-based biomaterials (20). The stability of a pharmaceutical formulation represents a key parameter, that indicates the storage-controlled conditions such as humidity, temperature, sun exposure. The modifications of samples color and electrical conductivity are displayed in table II.

pH measurements

The pH monitoring shows the almost neutral character of tested samples. The following results were obtained: 6.68±0.18 (sample PU_T1), 6.78±0.11 (PU_T2), and 6.71±0.14 (PU_T3).

TABLE II.

The changes of maximum absorbance and electrical conductivity levels in 30 days

Sample	Percentual changes at different temperature, %					
	8±0.5°C		25±0.5°C		40±0.5°C	
	abs.	cond.	abs.	cond.	abs.	cond.
PU_T1	4.3	7.5	4.0	7.0	4.1	6.5
PU_T2	4.5	7.9	4.2	7.7	4.3	7.6
PU_T3	4.4	8.3	4.2	7.9	4.2	7.8

Refractivity index

The values of refractivity index were: 1.59 for samples PU_T1, respectively 1.60 for samples PU_T2 and PU_T3.

Sample solubility

Table III displays the solubility of synthesized samples in different solvents.

TABLE III.

Comparative solubility of samples

Sample	Solubility (mg mL^{-1})		
	water	acetone	DMSO
PU_T1	0.87	1.07	1.09
PU_T2	0.79	0.99	0.92
PU_T3	0.75	0.93	0.86

Drug loading

The encapsulation efficiency represents the percentage of the biologically active compound that was successfully entrapped within the structures of the transporter / delivery system; the encapsulation efficiency and the controlled release behavior are the main parameters in this field and they depend most on the chemical structure and on the forces between molecules. In the current study, the average encapsulation efficiencies are equal to 63.7% (PU_T1), 58.1% (PU_T2) and 58.5% (PU_T3).

Drug release profile

The cumulated drug release is presented in second figure.

Penetrability rate

The penetrability through membranes represents the major rate-limiting step which have an impact on the release profile and further on the bioavailability of the active compound. A proper permeation through an artificial membrane was ob-

served for all samples (fig. 3), but the best results were recorded in the case of sample PU_T1 (more than 80% passed through the membrane in the first 2 days).

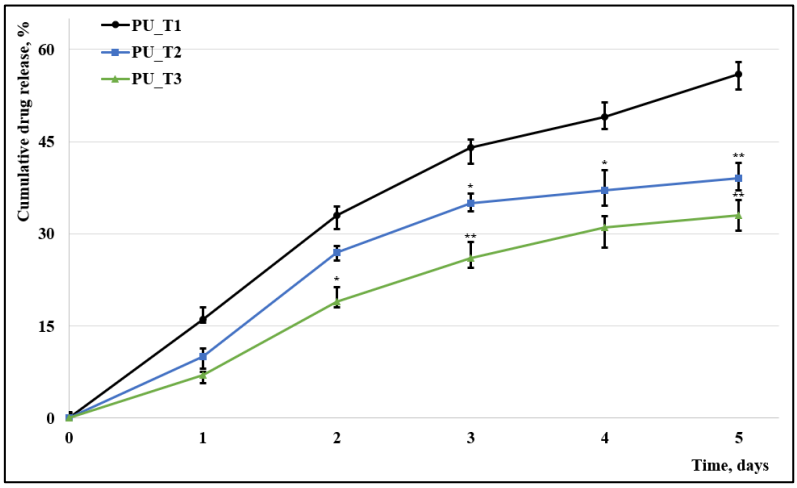

Fig. 2. Comparative cumulated drug release (mean ± SE); * for p< 0.05 and ** for p< 0.01 vs. PU_T1.

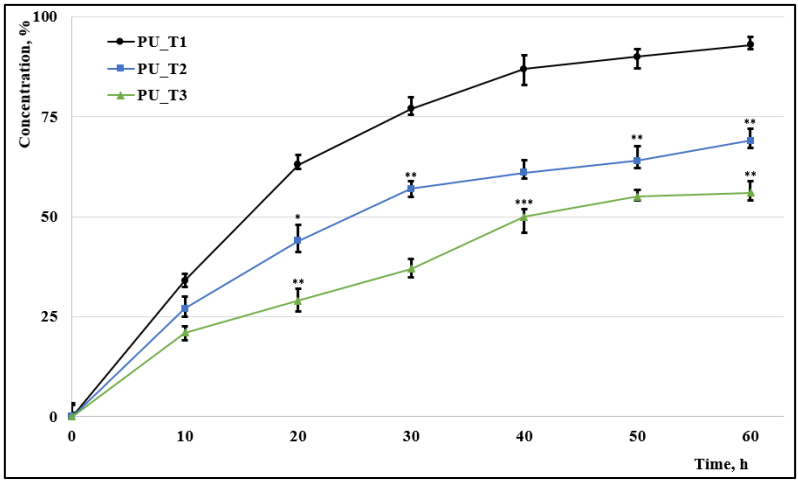

Fig. 3. Comparative penetrability rates (mean ± SE); * for p< 0.05, ** for p< 0.01, and *** for p< 0.001 vs. PU_T1.

Zetasizer

The analysis based on the dynamic light scattering is often used to characterize the colloidal suspensions and solutions; particles' size, their dispersity and surface charge represents important parameters in drug delivery too. Table IV shows the values obtained in the Zetasizer evaluations.

Table IV presents the formation of polydisperse systems containing two particle populations for samples PU_T2 and PU_T3, respectively a more homogeneous

system based on a single population of particles in the case of sample PU_T1; the average values of Zeta potential are also specific to systems with low resistance against the tendency to form particles cluster (for samples PU_T2 and PU_T3), while the value for PU_T1 is situated between medium and strong resistance (+34.4 mV).

TABLE IV.
Comparative Zetasizer characterization of samples

Sample	Analyzed parameters		
	Size (nm)	PDI	Zeta potential (mV)
PU_T1	162±7 (100%)	0.31	+34.4
PU_T2	126±11 (40%) 614±13 (60%)	0.87	+20.9
PU_T3	192±19 (29%) 814±23 (71%)	0.95	+17.6

Cells viability

In figure 4 are presented the HDFa cells proliferation rate.

The cells proliferation rates were studied at 24 and 72 hours (fig. 4). After 24h, a reduced inhibition was observed in samples PU_T2 and PU_T3, while sample PU_T1 exhibited an increased cell proliferation. At 72h incubation, in all samples, the same trend of stimulated cell proliferation was observed.

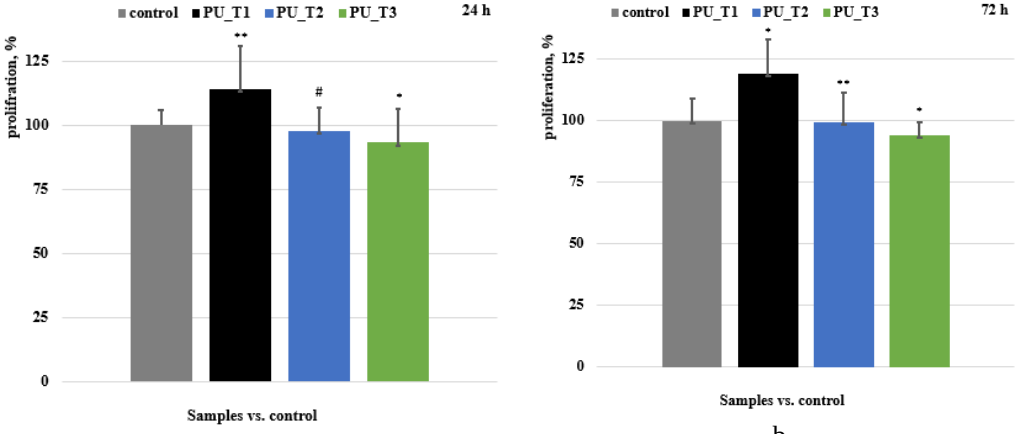

Fig. 4. Comparative cells proliferation (mean ± standard error) at (a) 24 and (b) 72 hrs.; # p= 0.0565, * p< 0.05, ** p< 0.01.

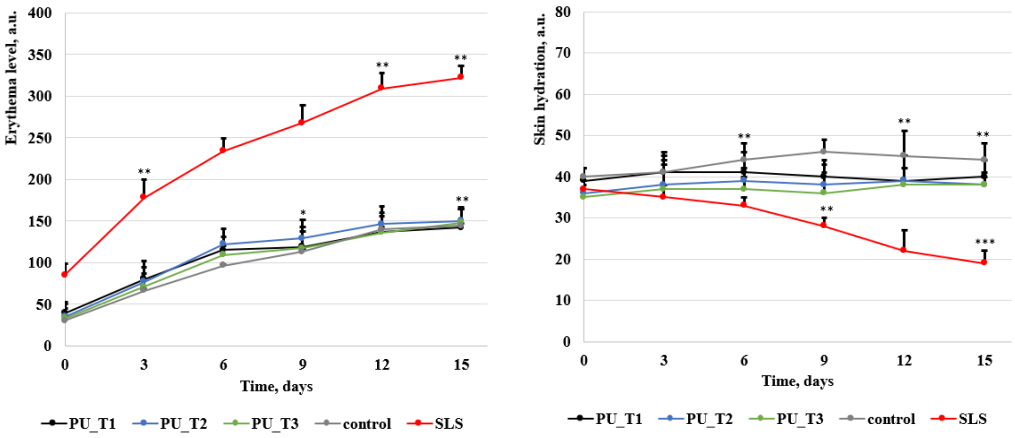
Skin Irritation Evaluation

Figure 5 presents the evolutions of two main skin parameters (erythema and skin hydration) during the 15-day experiment.

It can be noticed that the levels of erythema increased for all samples but these raises were much lower to that recorded in the case of sodium lauryl sulfate; on the other hand, the levels of the skin hydration (fig. 5b) have been modified only slightly in the case of mice treated with the synthesized samples.



a b

Fig. 5. Comparative changes of erythema and skin hydration (mean ± standard error); * p< 0.05, ** p< 0.01, *** p< 0.001.

DISCUSSION

A huge variety of polymers are obtained and tested as drug delivery systems in the administration of various extracts and drugs with low solubility and bioavailability (21, 22). Many PU carriers, as nanocapsules, dendrimers, and matrices, were developed in the last two decades; they were tested as delivery systems for ginger (13), garlic and mistletoe extracts (14), tocopherol (10-12), anti-tuberculosis drugs (23).

The temperature and pressure represent the main factors that have an important impact on the chemical synthesis and on the materials with special properties; the temperature influences the reaction rate and the equation between these parameters was proposed by Svante Arrhenius in 1889 (24). On the other hand, the temperature has a great impact on the volume: Jacques Charles stated that volume / temperature = constant (experiments on gases in the 1780s); in a similar manner, the most materials increase their volume when the temperature increases (they expand), except a few anomalies - the water between 0 and 4°C, super hard materials (25), multilayer steel (26), ceramics (27), rare-earth intermetallic with cobalt and iron (28).

Polymers present a wide range of linear thermal expansion; their coefficients are correlated with the type of intermolecular bonds. Their synthesis temperature depends on the exo- *vs*. endo-thermic processes that occur; thus, the requirements for polymerizations range from room temperature (29) till 100-200°C (30), polycondensation at 35°C (31), while polyadditions frequently exceed 90°C (32, 33). The synthesis of polyurethanes is based on a fast and exothermic reaction (34), so low synthesis temperatures, that were used in this study, can be an advantage.

The stability of polymer materials is well known and it is often the subject of waste issues. However, a few external factors, such as bacteria, water, temperature, and UV radiations, can accelerate their degradation. The results of the current study show that the obtained PU transport-

ers are stable between 8 and 40°C for 30 days, the changes of samples' maximum absorbance were between 4.0 and 4.5% for PU_T1 at 25°C and PU_T2 at 8°C, while the modifications of electrical conductivity were between 6.5 and 8.3% for PU_T1 at 40°C and PU_T3 at 8°C.

The pH of the samples, between 6.68 and 6.78, determined in aqueous solutions, is specific to nearly neutral acido-basic products. A narrow range of refractivity index (1.59-1.60) was found and it is very similar with other data reported in the literature (35).

The solubility is a significant drawback for all polymers; the current research revealed low values ranging from 0.75 mg mL^{-1} for PU_T3 in water to 1.09 mg mL^{-1} PU_T1 in DMSO. Generally, PU delivery systems present low solubilities which are often associated with a delayed release (36).

Important differences were found in the tested samples for the encapsulation efficacy, a key parameter in the design of drug transporters: PU_T1 sample has encapsulated almost 64% of the active agent, while the other two samples just 58%; the literature presents various values of the encapsulation efficacy between 40-91% (37).

The drug release profile is similar for the three samples, but higher values were found in the case of PU_T1: after 5 days, almost 60% of the encapsulated compound was released, while the other two samples present just 39 and 33%. The permeability of the PU transporters through an artificial membrane has revealed once again that the first sample (PU_T1), synthesized at the lowest temperature, is the best; almost the entire amount has passed through membrane within 60 hours.

Dynamic light scattering is often used as a technique proper to measure the particles' velocity to find their size, respectively the electrophoretic mobility to analyze their tendency to form clusters. The Zetasizer measurements (tab. IV) present a higher tendency to form particles' agglomerates and heterogeneous populations in the case of samples that were synthesized at higher temperature (PU_T2 and PU_T3).

The analysis of the proliferation of Human Dermal fibroblasts has indicated different trends among the samples: in the case of the first sample higher values was found (114% at 24 hrs. and 119% at 72 hrs.) compared to the second sample (98% at 24 hrs. and 99% at 72 hrs.) and the third one (93% at 24 hrs. and 94% at 72 hrs.). Based on these results, the samples can be considered as non-cytotoxic and more than that, in the case of PU_T1, it can be related to other studies that presents PU as friendly products with cells proliferation (38).

Due to their extremely sensitivity, mice are often used in the assessment of cosmetics, dermatological products, but also in testing of the irritation effects for newly synthesized pharmaceutical formulations. The levels of erythema have increased from approx. 35 to 145 arb. units; despite these increases, the three samples can be considered as safe products compared to the difference observed in the case of SLS (from 85 to 320 arb. units / same period). The decrease of hydration along with the increase of erythema and trans-epidermal water loss represent the main indicators of a skin disease or of an irritation effect; however, the amplitude of the change per time unit is important to be used in such assessment; the results show a maintained level of hydration in the case of samples with PU transporters, while the level de-

crease from 37 to 19 arb. units for SLS; based on the literature data (39), it can be stated that synthesized PU not alter the epidermal function.

CONCLUSIONS

Polyurethane materials are often used in medical and pharmaceutical applications as wound dressing, artificial skin, bone prostheses, heart valves, due to their biocompatibility. In the present study, a polyaddition reaction combined with a simultaneous emulsification was involved for the obtaining of PU particles that can be used as a carrier for nucleotides; the synthesis was done at three different temperatures in order to evaluate the impact on the final properties. The results indicate the preparation of a carrier that encapsulate large amounts of the active substance (around 60%), with a good release profile and a proper penetrability rate.

The physicochemical analysis showed that the sample prepared at 25°C (PU_T1) present the best encapsulation efficacy and the lowest tendency to form clusters that were observed compared to the other samples in Zetasizer characterization. Moreover, the sample prepared at the lowest temperature offers the best results in the cells viability, respectively in non-invasive tests on mice skin. Thus, the core finding of the current research is that a synthesis temperature below 40°C is suitable in the obtaining of a PU carrier for nucleotides.

Based on all the promising features previously described, the newly synthesized PU samples can be considered suitable candidates for the development of pharmaceutical formulations for delivery of nucleotides.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received financial support by "Victor Babes" University of Medicine and Pharmacy Timisoara, grant No. 5EXP/1244/30.01.2020

EXPLORING MYOCARDIAL BRIDGES CHARACTERISTICS IN NORTH-EASTERN ROMANIA: A RETROSPECTIVE ANALYSIS (Abstract): Myocardial bridges are defined by a segment of the coronary artery taking an intramuscular route, diverging from its usual superficial path over the myocardial tissue and, instead, traversing through the myocardium itself. Currently, their true prevalence remains uncertain and challenging to estimate accurately. Their dynamic presentation shapes the diversity of clinical manifestations, resulting in highly variable expressions among individuals. **Materials and methods:** We conducted a retrospective analysis of myocardial bridge characteristics in patients undergoing coronary computed tomography angiography (CCTA) at the "Prof. Dr. George I.M. Georgescu" Institute of Cardiovascular Diseases in Iasi, Romania, from 2012 to 2022. Additionally, we sought to investigate any potential correlation between the presence of myocardial bridges and the development of atherosclerosis and coronary artery disease. **Results:** Out of the 66 patients with myocardial bridges, 44 were males, accounting for 66.7% of the total cases. The average age was of 59.42 years (± 11.84 years). In 97% of cases, the left anterior descending artery (LAD) was affected, primarily at its middle segment (60.6%). The mean width measured 3.02±1.22 mm and the mean length was 20.33±9.25 mm. A significant elevation in the average calcium score level was observed among males (p=0.025). Individuals with myocardial bridge thickness over 5 mm showed significantly higher average calcium scores (p=0.025). **Conclusions:** Using CCTA improves the detection of clinically significant myocardial bridges, with the middle segment of the left anterior descending artery being the primary site in most cases. The study suggests a potential link between myocardial bridges thickness and higher coronary artery calcium scores, prompting further exploration. Correlations with atherosclerosis and hypertension require deeper investigation for a comprehensive understanding of myocardial bridges clinical impact. **Keywords:** MYOCARDIAL BRIDGES, CORONARY ARTERY ANOMALIES, ROMANIAN POPULATION, CARDIAC IMAGING.

INTRODUCTION

Initially documented by Reymann in 1737, myocardial bridging represents a congenital cardiac anomaly wherein a layer of cardiac muscle overlays a section of a coronary artery passing through the myocardium, forming a bridge-like configuration. This intramural portion of the artery, referred to as the "tunneled" artery, is surrounded by cardiac muscle tissue (1, 2). The prevalence of myocardial bridges varies depending on the diagnostic method employed. Post-mortem investigations yield the highest detection rate for myocardial bridges, ranging up to 86%, with an average of 25% (1). Invasive procedures like conventional coronary angiography can detect approximately 12% of myocardial bridges. Given the current inclination towards non-invasive approaches for identification, coronary computed tomography angiography (CCTA) emerges as the most accurate for assessing myocardial bridges. It provides superior capabilities in delineating the bridge's dimensions, as well as evaluating the degree of the induced compression (1). With various methods available to detect these anomalies, each differing in accuracy and specificity, the true prevalence of myocardial bridges remains uncertain and challenging to estimate accurately. However, there is a high likelihood that the actual prevalence of myocardial bridges exceeds current estimates (1). The predominant localization of myocardial bridges is typically within the left anterior descending artery (LAD), particularly evident in its mid-segment (3). When assessed using CCTA, myocardial bridges are categorized based on their depth: superficial (≥1 mm), deep (≥2 mm), and very deep (≥5 mm). Additionally, myocardial bridges are classified as short if their length is <25 mm and long if their length is ≥25 mm. This classification criterion aids in distinguishing between benign and clinically significant myocardial bridges based on their depth and length within the cardiac muscle (4). While the superficial and short myocardial bridges might usually be asymptomatic, those with a depth ≥2 mm and a length ≥25mm can have clinical manifestation that might vary from angina, heart block to acute coronary syndrome, syncope and even rarely sudden death (5). At the same time, recent studies aim to discern whether the presence of myocardial bridges exhibits a potential protective or detrimental effect on various cardiac conditions. Researchers analyzed the values of Ki-67 marker, assessing artery inflammation and atherosclerosis, and macrophages among the bridged segment of the coronary arteries (6). This study revealed their lower levels in the segments with myocardial bridges, compared to the other areas of the artery. Nevertheless, there are authors who contradict this hypothesis, suggesting that the existence of myocardial bridges could be a factor in determining coronary artery disease and therefore, ischemia (1). The diverse array of clinical expressions associated with myocardial bridges are significant given the absence of standardized guidelines for their identification, monitoring and treatment (7).

AIMS. Our study aimed to explore the characteristics of myocardial bridges observed in patients seeking care at "Prof. Dr. George I.M. Georgescu" Institute of Cardiovascular Diseases, over a decade within the North Eastern region of Romania. Additionally, we sought to investigate any potential correlation between the presence of myocardial bridges and the development of atherosclerosis and coronary artery disease. The motivation for our investigation started from the limited existing research on

the prevalence and attributes of myocardial bridges within the Romanian population. This gap in knowledge highlights the importance of our study in contributing to a deeper understanding of cardiovascular anomalies within this specific demographic.

MATERIALS AND METHODS

Study design and patients

Our research investigated a cohort of 12,758 patients with cardiovascular diseases who underwent coronary computed tomography angiography (CCTA) from 2012 to 2022 at "Prof. Dr. George I.M. Georgescu" Institute of Cardiovascular Diseases from Iasi, Romania. The information employed in this study was obtained from the medical files of the patients. The acquired data facilitated the categorization of the enrolled cohort into various groups based on anomalies of the coronary arteries, with a primary focus on myocardial bridges. Our database included demographic variables including the age and gender (female/male) of the patients, all of whom were adults. Simultaneously, we documented the presence of coronary artery disease, chronic cardiac failure, dyslipidemia, hypertension and coronary angioplasty with stents. The study design and protocol were approved by the Ethics Committee of "Grigore T. Popa" University of Medicine and Pharmacy Iasi, Romania (no. 115/15.10.2021).

CCTA Assessments (Myocardial Bridges and Agatston score)

In this investigation, we initially incorporated data concerning the affected coronary artery by myocardial bridges, along with detailed characteristics regarding the depth and length of these structures. All measurements pertaining to these parameters were recorded in millimeters (mm). Subsequently, our classification scheme stratified myocardial bridges into three distinct categories based on depth: superficial (<2mm), deep (≥2 and <5), and very deep (≥5 mm). Regarding length, we defined two categories relative to a threshold of 25 mm: those falling below this threshold were categorized as short, whereas those equal to or exceeding it were classified as long. Concurrently, we documented the presence of atherosclerosis and consecutively assessed the degree of stenosis in the affected coronary artery with myocardial bridge, classifying stenosis in non-critical if the diameter of the coronary artery was <70% and critical if it was ≥70%.Furthermore, we integrated the Agatston calcium score into our database, categorizing it into four different groups: 0. no atherosclerosis (0 Agatston units), 1. mild (1-100Agatston units), 2. moderate (101-400Agatston units) and 3. severe (>400Agatston units).

Statistical analysis

Data were collected and subjected to analysis using the *Statistical Package for Social Sciences version 27.0* (IBM Corp., Armonk, NY, USA). Specifically, the analysis utilized the ANOVA test, a widely recognized method for examining variance across multiple groups. Primary indicators such as the minimum and maximum values, along with frequency distributions, were examined to gain insights into the range and distribution of the data. Indicators of central tendency including the simple arithmetic mean and median were calculated to understand the average or typical value of the dataset. Indicators of dispersion, such as the standard deviation and standard error, were computed to assess the spread or variability of the data points around the mean. Additionally, confidence intervals of the mean were determined to quantify the precision of the estimated

population parameters. Qualitative significance tests were conducted to examine the significance of categorical variables within the dataset. All analyses maintained a significance level of $p < 0.05$.

RESULTS

Among the examined patients, 350 (2.74%) exhibited coronary artery anomalies, and among them, 66 were diagnosed with myocardial bridges (18.9%). Out of the total cohort, 44 were males, constituting 66.7% of the patients, while 22 were females, accounting for 33.3% (fig. 1).

The age ranged from 22 to 84 years, with an average level of 59.42 years ± 11.84 years, which is relatively close to the median value (60.50 years) (fig. 2).
